Usually, the ureteroscopy begins with a cystoscopy. As Sun's ureterorenoscope offers satisfactory image quality, it could be used for full assessment of the bladder instead of using a rigid cystoscope. After the relevant ureteral orifice is located, a 0.035 inch hybrid guidewire is advanced through the ureteroscope to access the ureter. If a small orifice is encountered, the endoscope could be rotated 180° to lift the ureteral orifice, enlarging the space into which the ureteroscope advances. In addition, balloon dilators can also be used, allowing the scope to access across the small orifice with ease. In most causes, there is no need to worry about ureteral injuries, as a recent study suggested that balloon dilatation is not a risk factor for ureteral wall injury during ureteroscopy [22]. A second ureteroscopy after 1–2 weeks of double-J stenting should also be considered if the ureter is so small that any ureteroscope access attempt would cause severe ureteric injury.

Generally, scope access to the orifice is followed by a retrograde pyelogram procedure [23]. However, if ureteroscopy is being performed for treating mid or distal ureteral stones, a pyelogram might be skipped as there is no need to determine the layout of the collecting system and it has a potential risk of stone retropulsion as well as unnecessary increased radiation exposure. For safety, the guidewire is advanced gently under X-ray guidance and endoscopic vision. After the guidewire is properly placed, Sun's ureterorenoscope is then advanced alongside the wire with great caution. If there is any resistance, the temptation to push the ureteroscope should be avoided without identifying the caliber of the ureter.

Occasionally, due to severe tortuous ureteral conditions caused by stone obstruction or anatomical features, advancement of the ureteroscope might be particularly challenging. Under such circumstances, the Trendelenburg position is useful as it moves the kidney to the head side which will decrease ureter tortuosity. Other tips such as pressure on the abdomen could also be helpful for straightening the ureter.

During conventional semirigid ureteroscopy, once the ureteral stone is visualized the guidewire is widely recommended to pass across the stone obstruction and coil in the renal collecting system as a safety wire. This will not only maintain access to the upper urinary tract but also straighten the tortuous ureter. As for Sun's ureterorenoscope, if there is no potential risk of iatrogenic injury, the safety guidewire can be omitted. Benefiting from the three-stage retractable configuration of the outer sheath, the deflectable tip of the Sun's endoscope can be extended out in three different lengths in order to accommodate different requirements (see Figure 41.5). This unique design allows the flexible tip to deflect in a rather small range without losing rigidity, and is useful when treating difficult ureteral stones in particular. With this slight deflection, a better line of sight is likely to be obtained and the laser fiber can be placed onto the stone's surface instead of the ureteral mucosa, even when there is no safety guidewire left in place.

When the tip-flexible ureteroscopy is performed for intrarenal endoscopic surgery, the retrograde pyelogram should be performed to delineate the collecting system map. After Sun's endoscope is advanced and has reached the ureteropelvic junction, the assistant helps to inject

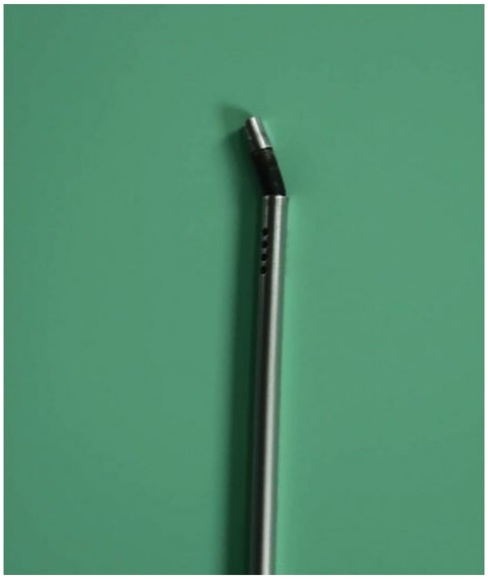

**Figure 41.5** The deflectable tip of Sun's ureterorenoscope can be extended to a variety of lengths.

the diluted contrast medium through the working channel. A retrograde pyelogram should be visualized dynamically to control a proper contrast dose, whereby a clearly visible collecting system anatomy and renal stones are identified without causing contrast extravasation.

Before using the deflectable tip of Sun's ureterorenoscope to inspect the kidney, the outer rigid sheath should be fully retracted to extend the entire 90 mm inner deflectable tip. Movement of the deflectable shaft is carried out using two synchronized methods. Active deflection (up and down) is manipulated by the lever on the handpiece, and horizontal steering is controlled by axis rotation of the endoscope. Under the guidance of the retrograde pyelogram, inspection of the collecting system progresses from the renal pelvis to the upper, middle, and lower renal calyces.

During the procedure, the assistant should maintain proper saline irrigation using a syringe to provide optimal visualization. Over-pressurizing should be avoided as it might cause pyelovenous backflow and secondary infection. Care should be taken to ensure continuous outflow at the outlet port. If outflow stops then it suggests that the edge of the rigid sheath has not passed across the level of ureteropelvic junction and that the position needs to be adjusted.

## Lithotripsy

After the ureteral or the renal stones have been located, lithotripsy should be performed. Since Sun's ureterorenoscope has an active deflectable tip that can be used for treating calyceal stones, holmium:YAG laser is the best lithotripsy equipment in tip-flexible ureteroscopy. Among the available varieties of laser fibers, 200 μm laser fiber is mostly recommended, as its small diameter has very limited impact on endoscope deflection as well as on adequate irrigation. Additionally, 200 μm laser fiber carries up to 45 W power, which is capable of disintegrating or ablating all stones irrespective of composition. By now, most urologists have accepted the standard of "stone free," defined as residual fragments not exceeding 4 mm by X-ray. Since fragment retrieval does not suit tip-flexible ureteroscopy, stone particles must be small enough to ensure complete postoperative expulsion. Therefore, "stone dusting" is preferred as the ideal lithotripsy modality for fragmentation in tip-flexible ureteroscopy, Generally, laser power should be initially set to a "low energy/high frequency" mode of 0.5–1.0 J/20–30Hz, which will suit stone dusting and vaporization. If the stone is hard, the power is increased to 1.0 J at 10 Hz. One thing to always be aware of is that the laser fiber should be advanced when the deflectable tip is in a straight position instead of being deflected, so as to avoid scope or working channel perforation of the surrounding tissue. Laser lithotripsy should be synchronized to respiratory movements, thus avoiding injury to the mucosa. In patients with significant respiratory movements, temporary breath holding with assistance from the anesthetist might facilitate accurate stone fragmentation.

Sung et al. reported that lower calyceal stones contributed to approximately 49% of total renal stone cases and had a worse SFR than upper and mid calyceal stones [24]. This result suggested that lower pole stones are not only the most commonly encountered cases, but also are the most difficult scenarios for ureteroscopy. Despite certain tests demonstrating that Sun's ureterorenoscope has satisfactory deflection, it is recommended to perform stone relocation before fragmentation, as it reduces the duration of the endoscope working in maximum deflection. Working instruments such as baskets and graspers should be used to move the lower calyceal stones to a more favorable position such as the mid or upper calyx.

After complete lithotripsy, a final retrograde pyelogram should be performed to determine whether any calyx is missed on entry. Sun's ureterorenoscope should be withdrawn, with its deflectable tip kept in the neutral position. The rigid sheath of the scope should be retracted during this procedure, and should not be extended until the endoscope has been withdrawn completely.

A double-J stent placement is recommended in some complicated situations, including large stone burden, a tight ureter, evidence of extravasation, and solitary kidneys.

## Technical failure

Since the majority of the ureterorenoscope shaft is covered by metal, it has a low risk of shaft damage in comparison with its flexible counterparts. Based on the results from a multicenter study by Yinghao Sun [8], and our experiences, the average usage for Sun's endoscope before major repair is over 60 procedures. A broken shaft at the rigid/deflectable junction contributes to the majority of endoscopic failures. There are several principles that are helpful in maximizing the ureterorenoscope's life span. Firstly, the endoscope should not be advanced through the ureter with the outer sheath fully retracted. The view from the endoscope indicates only whether there is any obstruction directly beyond the tip; if the sheath is retracted operators will not be aware if a junction site has already buckled the tip, or to what angle. This is the most common failure for surgeons who are not familiar with the endoscope's features in particular. Secondly, the outer sheath should never be extended *in vivo* once it has been retracted in the procedure. Sheath extension must be performed with the deflectable tip in the straight position, under direct vision when it is fully withdrawn outside the body. Thirdly, overdeflection and prolonged duration in lower pole calyces should be avoided when accessing the lower pole calyces, especially with a working instrument inside. This might lead to the active deflection unit being broken.

### Care, maintenance, and sterilization

After utilization, the outer sheath and the inner shaft of Sun's ureterorenoscope should be dissembled and carefully cleaned. The deflectable tip should be maintained in the straight position to avoid damage and degradation of its deflection angle. A leak test should always be performed before and after every utilization, ensuring that minor damage to the shaft or the working channel is not neglected. During gas sterilization, the venting system, mostly via a valve, should be equipped to equalize pressures and prevent damage to the scope.

## Future trends

Similar to semirigid and flexible ureteroscopes, Sun's ureterorenoscope is under constant development towards smaller caliber, better image quality, and better deflection. To improve deflection for access to lower pole calyces with a very difficult ureteroinfundibular angle or great infundibular length, the latest version has been developed with an additional passive flexible part. It is undergoing perspective study. Future improvements, including the use of digital video technology, are under consideration.

*Department of Urology, Haseki Training and Research Hospital, Istanbul, Turkey*

## Introduction

Flexible ureteroscopes are widely used in daily practice by urologists for treatment of calculi and for diagnosis and treatment of ureteral and upper urinary system disorders. The less invasive nature of the procedure makes it a favorable choice for surgeons compared with more invasive alternatives such as percutaneous nephrolithotomy or even other minimally invasive techniques. Since its introduction, many technological advancements have been made. Better imaging quality and deflection angles, more functional working channels, and more durable instruments have been introduced. Currently, flexible fiber-optic ureteroscopes, flexible digital ureteroscopes, and the recently introduced disposable digital flexible ureteroscopes are all being used in daily practice. In this chapter we review the details of digital ureteroscopes, which have a characteristic advantage of superior imaging thanks to their "chip on the tip" technology.

## Reusable digital flexible ureteroscopes

Digital flexible ureteroscopes are widely used in clinical practice and stand out because of their enhanced high-quality images. Previous ureteroscopes transmitted images via fiber-optic cables, with an external light source and an attached camera. Today's digital ureteroscopes do not necessitate such bulky devices; instead, digital images are transferred to a screen via a single cable (Figure 42.1). This feature reduces the effort required by the surgeon, and better quality images make the operation easier to perform. Pixel resolution of digital ureteroscopes is nearly ten times better than that of fiber-optic ureteroscopes and the images can be magnified digitally and viewed during the operation (Figure 42.2). ACMI DUR-D Invisio was the first digital flexible ureteroscope introduced for urologic practice. It contained a complementary metal oxide semiconductor (CMOS)-based chip at its distal end. Even though ACMI DUR-D had better image resolution than previous ureteroscopes, there were some disadvantages, such as increased instrument diameter. This sometimes prevented the surgeon from reaching the desired lower calyx and produced a deteriorated image when the red laser beam was activated. Technological advancements have led to the production of newer and better quality digital ureteroscopes. The Olympus URF-V, which contains a charge-coupled device (CCD)-based chip, and the Karl Storz Flex-Xc, which contains a CMOS-based chip, were introduced in the following years.

Better contrast discrimination, color differentiation, and higher-resolution images obtained by digital ureteroscopes lead to better diagnosis of millimetric lesions and increased comfort for the surgeon during renal stone fragmentation. Focusing on the stone and identifying the calyceal anatomy is much easier with these ureteroscopes, which leads to decreased risk of mucosal injury and bleeding during stone fragmentation with a holmium laser (Figure 42.3). Enhanced imaging achieved by digital ureteroscopes also decreases the operation time when compared with fiber-optic ureteroscopes [1].

Although technological advancements have led to better quality images and more durable ureteroscopes, there are still certain problems owing to the fragile nature of these instruments. Many studies have compared the durability of digital ureteroscopes with fiber-optic ureteroscopes and have proven that digital ureteroscopes are more durable. However, flexible ureteroscopes are all fragile instruments. Repetitive use of these instruments

eventually decreases the angle of maximal deflection. Proper handling of the instruments by experienced surgeons significantly increases their durability. Use of an access sheath during the introduction of the instrument into the upper urinary tract also increases its life span. Avoidance of maximal deflection and relocating stones before fragmentation are also beneficial precautions. Another problem with these instruments is possible damage to the digital chip and ureteroscope by the holmium laser if unintentionally retracted into the instrument during stone fragmentation. Turning the laser off while retracting it into the ureteroscope or fixing the laser after appropriate placement are possible precautions, but they are not guaranteed. Use of an "endoscope protection system" (EPS) is a better option. When the laser is retracted into the instrument, and therefore disappears from sight of the CMOS-based chip, the EPS recognizes the absence of the blue cladding of the active laser fiber and automatically switches it off. All of these precautions lead to increased life span of these expensive instruments and reduce repair costs.

Digital ureteroscopes have become the subject of many studies. Newly introduced "chip on the tip" technology, superior imaging quality, newly introduced working channels, and maneuverability abilities are the main features that have been evaluated. Binbay et al. and Somani et al. made a comparison between digital and conventional ureteroscopes, discussing the slightly limited maneuverability and shorter operation times of digital scopes [1, 2]. Shah et al. compared the ACMI DUR-D with the Olympus URF-V and found better visibility and maneuverability of the CCD-based Olympus URF-V [3]. Lusch et al. compared the performance and characteristics of the dual-channel Wolf Cobra fiber-optic ureteroscope with two single-channel fiber-optic ureteroscopes and a single-channel URF-V digital ureteroscope. They found better image resolution with the URF-V owing to its digital sensor chip and increased irrigation flow of the Wolf Cobra as a result of its separate working channel. They also noted the increased thickness of the Wolf Cobra when compared with other ureteroscopes [4]. Richard Wolf has since introduced a digital version of this unique instrument called Cobra Vision. Technical details of available digital ureteroscopes are listed in Table 42.1.

Humphreys et al. [5] published a unique article about the use of these novel digital ureteroscopes. They conducted this study using the ACMI DUR-D digital ureteroscope and mentioned the possible use of these instruments, which produce high-quality images, in detecting the early stages of calcium oxalate stone formation and possibly understanding the mechanism of stone formation [5]. Multescu et al. compared the Flex-Xc, URF-Vo, and Wolf Cobra in terms of maneuverability, imaging, and deflection mechanisms. They stated that the most important difference was image quality, but another important difference was the more effective irrigation flow of the Wolf Cobra [6]. Bach et al. compared the need for an access sheath in two different ureteroscopes, the ACMI DUR-D digital flexible ureteroscope and the DUR-8 fiber-optic flexible ureteroscope. They noted an increased need for ureteric access sheath use with digital ureteroscopes due to their increased tip diameter, which may increase morbidity and cost of the operations [7].

## Disposable digital flexible ureteroscopes

The high price and repair costs of flexible ureteroscopes led to the creation of disposable, single-use versions. Bagley first introduced the flexible disposable modular ureteropyeloscope in 1987 [8]. This ureteroscope contained a replaceable flexible tip, available in 6.0, 8.5, and 11.0 Fr diameters. He cited his indications for the use of this disposable instrument as surveillance for fragments after lithotripsy and for diagnosis of radiographic abnormalities in the upper tract. He introduced the instrument into the ureter successfully in 37 out of 38 patients, a promising success rate. In 2009, Boylu et al. compared the efficacy and quality of the disposable flexible SemiFlex Scope, which contains a reusable eyepiece and a semiflexible shaft with a 3.3 Fr working channel, with currently used fiber-optic ureteroscopes [9]. They noted that the SemiFlex Scope had acceptable features and showed promising results. A year later, the PolyScope, a semidisposable flexible ureteroscope, was evaluated by Bader et al. [10]. They mentioned the lower costs of this instrument compared with the high repair costs of other reusable flexible ureteroscopes. The more recently introduced Boston Scientific LithoVue single-use digital flexible ureteroscope is a newer disposable ureteroscope and stands out because of its high resolution images provided by the digital CMOS-based chip at its distal end (Figure 42.4). The tip diameter of the scope is 7.7 Fr and the outer diameter is 9.5 Fr. It offers 270° deflection in both directions and similar image quality to other reusable scopes. It contains a built-in light source and is connected to a rolling mobile workstation with a single cable. The workstation contains integrated image-transferring software and provides high-definition images. Life span of these instruments are restricted with 4 hours of usage by the producer. Proietti et al. compared the efficacy of the newly introduced LithoVue disposable digital ureteroscope with the reusable URF-V digital ureteroscope and the URF-P5 fiber-optic ureteroscope, and stated that the LithoVue is comparable with other conventional ureteroscopes in terms of visibility and manipulation [11] (Figures 42.5 and 42.6). Because this technological device was recently introduced, their cost-effectiveness and usefulness remains to be analyzed with further clinical trials.

## Technical features of digital ureteroscopes

### Setup

Digital ureteroscopes differ from standard flexible fiber-optic ureteroscopes, especially in image-transfer technologies. A digital ureteroscope is composed of a proximal handle and an articulation lever at its proximal end, similar to standard flexible ureteroscopes. Digital ureteroscopes are connected to a digital high-quality screen and light source without the need for an additional optical eyepiece or a camera head. The distal end of the cable attaches both to the light source and to the video monitoring system and

data are transferred to the monitor. The Olympus URF-V and URF-V2 have an additional illumination cable attachment using a newer technology, which is discussed under Illumination, below. Two working channels are available on these ureteroscopes; one is used for irrigation and the other for instrumentation. Access sheaths are placed into the desired ureter via guidewire placement and the rest of the procedure is similar to standard flexible ureteroscopy. Disposable digital ureteroscopes also have similar properties but have a single attachment cable to their unique monitoring system, which includes the illumination device.

## Imaging

A unique feature of digital ureteroscopes is their enhanced imaging ability. They achieve this better imaging with a chip at their distal end, and thereby this feature is called “chip on the tip” technology. The first flexible ureteroscopes were introduced in the early 1960s and delivered the image to a screen via fiber-optic cables. Each fiber-optic cable delivered a certain part of the entire frame, giving the final image a “honeycomb” or “chicken wire” appearance. These fiber-optic flexible ureteroscopes are still used widely. In 1969 at AT&T Bell Labs, Boyle and Smith invented a microchip that transfers information by storing an electrical charge in itself, allowing the data to be retrieved when desired, and thus creating digital imaging and image-transferring technologies [12]. These microchips are called CCDs and won Boyle and Smith the Nobel Prize for Physics in 2009. These devices convert incoming photons by p-doped metal oxide semiconductor (MOS) capacitors into an electrical charge, and then convert this information into a digital format. Another similar technology called CMOS was patented by Frank Wanlass in 1963 and also used for digital image transferring purposes [13]. CMOS chips are semiconductor battery-powered chips which store information and are used in computers as microprocessors, data converters, and image sensors. Both of these technologies are being used in many different fields, but they were first used for medical purposes in

2005 for the ACMI DCN-2010 digital flexible cystoscope. This device allowed better visualization and provided better images of the urethra and bladder. A year later, in 2006, the ACMI DUR-D digital ureteroscope was introduced, which carried a CMOS chip at its distal end (chip on the tip technology). Different digital flexible ureteroscopes carrying CCD or CMOS chips have since been introduced.

### Illumination

Illumination is mandatory for flexible ureteroscopy, as it is in all endoscopic procedures. Illumination is achieved through a light source connected to the flexible ureteroscope. In fiber-optic scopes, this connection was achieved by plugging in one end of the light cable to the illumination unit and the other end to the instrument. In digital scopes, there is no additional plug-in unit on the instrument. The distal ends of digital ureteroscopes have a socket that is plugged into the control unit, which is responsible for both image transferring and illumination. However, the Olympus URF-V and URF-V2 have an additional extension of this single cable that is separately plugged into the illumination unit and uses different illumination technology than the others (Figure 42.7). Most digital ureteroscopes use light-emitting diode (LED) technology, whereas the Olympus digital ureteroscopes use xenon technology for illumination. The additional cable extension is connected to a xenon light source. Prospective trials are needed to evaluate any functional differences between LED and xenon illumination.

### Deflection mechanism

Another unique feature of flexible ureteroscopes is their deflection ability. The distal end of flexible ureteroscopes can deflect up to 275° and this deflection is controlled by a lever located at the proximal part of the instrument. This type of deflection is called "active deflection." Small wires are present between the distal part and the lever, and movement of these wires creates up and down deflection of the distal scope. The first flexible ureteroscopes only had the ability to deflect 170°.

Another type of deflection is called "passive deflection," achieved by the contact of the intrarenal collecting system with a softer segment of the instrument located proximal to the deflecting region. This softer segment allows additional deflection and facilitates reach of the entire collecting system.

Rotation of the instrument during the operation allows the surgeon to relocate it by changing the shaft's angle and increase the maneuverability. This maneuver is achieved by inward or outward rotation of the surgeon's hand. As an example, while fragmenting a large stone, rotating the instrument will change the position of the laser fiber and thereby facilitate effective stone fragmentation. This manual hand maneuver can be challenging for surgeons after longer operation times. The Olympus URF-V2 digital flexible ureteroscope overcame this problem by adding a special rotation control ring to the distal part of the handle. This ring achieves 120° of rotation to the left and right, and aims to reduce the effort required by the surgeon.

## Care, maintenance, and sterilization

Flexible ureteroscopes are delicate and expensive instruments and are more fragile than semirigid and rigid ureteroscopes. Proper handling and careful sterilization are very important for extending the life span of these instruments. Fiber-optic flexible ureteroscopes had the

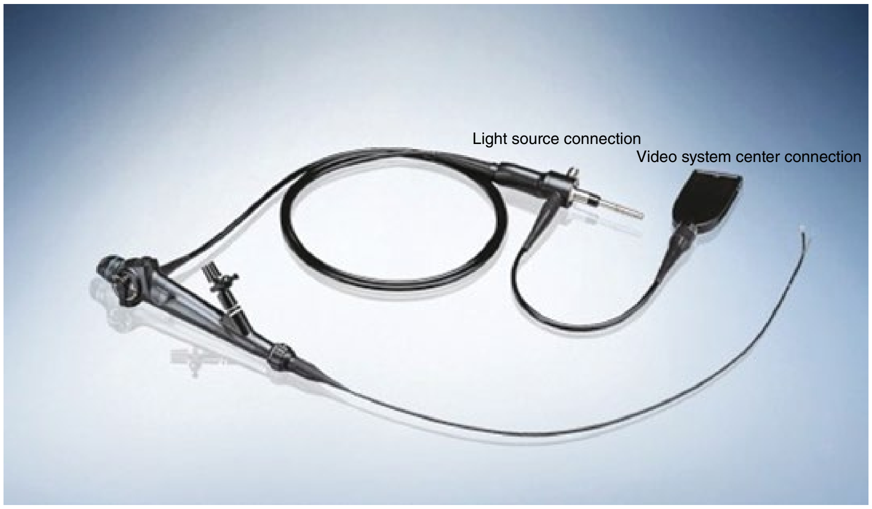

**Figure 42.7** Olympus URF-V connection cables.

disadvantage of easily damageable optic fibers, but the CDC and CMOS technology and lack of optic fibers avoids this flaw in digital ureteroscopes. When even a single fiber of a flexible fiber-optic ureteroscope becomes damaged, the part of the image frame it covers does not appear on the screen, resulting in an incomplete image. Even though this optical fiber problem is solved in the newer technology, there are many other ways these instruments can be damaged. Over-deflection of the instrument, especially during the struggle to reach the lower calyceal system with a narrow infundibulopelvic angle, loose handling, retracting the active laser fiber into the instrument, and inappropriate cleaning sterilization and storage methods are all typical ways in which these instruments can be damaged. Well-trained operating room staff, residents, and specialists are crucial for increasing the life span and durability of flexible digital ureteroscopes.

The experience of the surgeon is a very important factor in the durability of these instruments. A study published by Binbay et al. compared the durability of the Karl-Storz Flex X2 with the ACMI DUR-D, and found equal need for repairs when operations were performed by equally experienced surgeons [1].

Another potential cause of damage is introduction of the laser fiber into the instrument. The laser fiber should be introduced into the instrument only if the instrument is in a fully straight position, which can be confirmed by fluoroscopy. If the laser fiber is introduced when the instrument is deflected, the tip of the laser fiber can cause serious damage to the working channel and to the shaft of the instrument. Another way to improve the durability of both the instrument and the laser fiber is to use high-frequency, low-energy settings during laser fragmentation. This energy setting prevents breakage of laser fiber inside the instrument. Using a safe seal port is also beneficial. Fixing the laser fiber gently by this safe seal port prevents the laser fiber from retracting into the instrument and causing further damage. Before starting laser fragmentation, the focus point of the laser fiber on the stone should be confirmed to avoid damage to the distal end of the instrument and to the epithelium of the renal collecting system. Some areas of the collecting system can be very hard to reach with flexible ureteroscopes and surgeons should keep in mind that there are alternative methods like shock-wave lithotripsy or percutaneous nephrolithotomy to clear these stones. Applying too much pressure and torque on the instrument to reach the calyx will decrease its life span. Offering other treatment modalities to patients is another way to increase the instrument's life span. Placing an access sheath in the ureter before introducing the instrument will also help avoid damage and is highly recommended. After the introduction of the instrument through the access sheath, the outer portion of the instrument should be kept as straight as possible and extreme bending of that portion should be avoided to avoid unintentional laser fiber injuries and to increase the durability of the instrument. Flexible ureteroscopes should be used for appropriate cases and their advantages, disadvantages, and cost-effectiveness should be evaluated on a case-to-case basis.

Proper maintenance and sterilization of these instruments are as important as their surgical handling. A dedicated and experienced sterilization staff is mandatory. Unnecessary bending and deflection of the instrument should be avoided during sterilization. Instruments should be stored in their special cases. Use of formaldehyde should be avoided, as it may cause damage.

Flexible ureteroscopes have the advantage of having a deflection mechanism at their tip. This enables the surgeon to reach the desired calyx and make appropriate movements during surgery. However, this advantage can turn into a disadvantage if over-deflection occurs. This situation typically occurs during maneuvers to reach the lower calyceal system. Karaolides et al. mentioned this problem [14]. Most of the instrument injuries and repair needs occurred after over-deflection. They also mentioned that these instruments needed repair after an average of 18 uses and that appropriate handling and monitored training of new users can decrease the chance of damage and increase the life span of the instruments. As a result, Karaolides et al. concluded that overall longevity depends on correct handling and appropriate training of surgeons. Multescu et al. also noted this [15]. They evaluated patients who underwent flexible ureteroscopy with a Storz Flex-Xc flexible ureteroscope and advised the importance of using a ureteral access sheath, avoiding over-deflection, and relocating lower pole stones when possible. They concluded that these preventions prolonged the life span of the instruments. They also cited the importance of removing the flexible ureteroscope en bloc with the access sheath, to avoid damage to the tip of the instrument if it is deflected and comes in contact with the distal end of the access sheath.

When the ACMI DUR-D was introduced, it had a certain disadvantage during laser fragmentation referred to as the "sunset effect" (Figure 42.8). The tip of the laser fiber appeared as a red light, which indicated the active state of the laser fiber. This red light caused a prominent glare and visual artifact not seen with other flexible ureteroscopes. This sunset effect made it more difficult to focus on the stone and caused trouble for surgeons during stone fragmentation. Surgeons generally overcame this problem by deactivating the red light of the laser fiber, which posed possible damage risk to the instrument if the laser fiber was broken. The surgeon would not be aware of laser malfunction because of the always-inactive

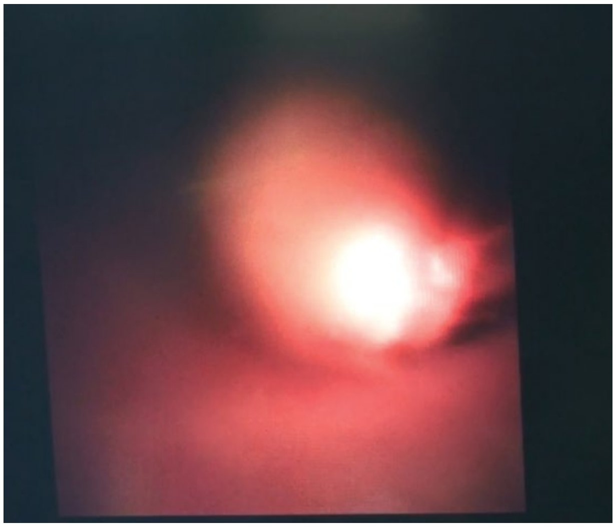

Figure 42.8 Sunset effect during ureteroscopy.

red light. The ACMI DUR-D flexible ureteroscope also caused artefactual images during fluoroscopy screening, but both these unwanted images and the previously mentioned sunset effect have been overcome in newer digital ureteroscopes.

There are other avenues for possible instrument damage during use. Retracting the laser fiber into the instrument during stone fragmentation may cause serious damage to the working channel and inevitably require repair. The traditional way to overcome this problem is referred to as the "safe laser technique" and is achieved by fixing the proximal end of the laser fiber to the entrance part of the working channel by screwing it to the distal part of an adjustable Tuohy-Borst adapter. EPS can also be used to prevent this situation, terminating the laser energy when the laser fiber is retracted into the ureteroscope. Sung et al. evaluated the efficacy of this system in an *in vitro* study and found it highly effective, except in situations of high-density blood concentration [16]. Xavier et al. also evaluated the efficacy of this system in an *in vivo* study and concluded it to be highly effective and able to replace the standard safe laser technique [17].

## Conclusion

Digital technology is widely used in medical and nonmedical fields and it keeps developing day by day. Digital ureteroscopes are being used by urologists with high success and low complication rates. Better imaging quality can reduce operation times. Overcoming the issues about high repair costs of these instruments, developing more effective stone fragmentation methods to treat bigger stones, and creating thinner instruments will replace fiberoptic ureteroscopes with digital ureteroscopes completely.

## Introduction

Before the collaborative efforts between engineers and urologists spurred by the birth of endourology in the early 1980s, upper urinary tract diseases were managed through large open incisions and were associated with significant associated patient morbidity [1]. The advent of flexible and semirigid ureteropyeloscopy has lead to less invasive treatment options for the upper collecting system. Over the course of time, lead by the interaction between engineering and medicine, the instrumentation and technique of endourology has continued to be refined and improved.

## Patient preparation

After induction of anesthetic, the patient is placed in a lithotomy position with the ipsilateral leg slightly extended [2]. Although recommended primarily for patients with a moderate risk of thromboembolism [3], we routinely utilize pneumatic compression boots in all patients in the lithotomy position to decrease the risk of deep venous thrombosis and decrease the risk of intra-compartment pressure [4].

The C-arm monitor, video monitor, and holmium laser machine are positioned on one side of the patient such that the surgeon's attention to the C-arm image, endoscopic image, and laser foot pedal are all "in line," requiring little movement of the head but rather subtle movement of the eyes. It is helpful to utilize software that draws the fluoroscopic image into a "picture-in-picture" format on the endoscopic image. Typically a flat-screen monitor mounted on a swivel arm is utilized. The C-arm device is positioned on the other side of the patient to allow for free movement of the image intensifier from the kidney to the pelvis.

On occasion, if there is uncertainty as to whether the pathology may require a percutaneous approach, the patient may be positioned in a prone-split leg position, so that it is easy to proceed with posterior percutaneous renal access if needed [5].

## Ureteral access

The use of a safety wire is encouraged for all urological endoscopic procedures, although some authors suggest it is not needed if active stone basketing is not planned as part of the procedure [6]. Guidewires facilitate and maintain access to the upper urinary tract and may straighten an otherwise tortuous path. The ideal guidewire would require little force to bend in response to obstruction, and a large force to perforate through tissue. These properties were examined in an *in vitro* study with nine commercially available guidewires and the lubricous, soft-tip nitinol Glidewire (Boston Scientific, Natick, MA, USA) was the safest wire for initial access to the ureter, as it is less likely to perforate and more likely to bend before a point of obstruction [7]. Another study has evaluated a new set of straight-tip hydrophilic guidewires that has been recently launched in the market based on the same properties as described later and in comparison to Glidewire (Boston Scientific). The Glidewire and the EZ Glider (Olympus) required the most force to perforate the *in vitro* model and presented the lowest tip bending forces. Moreover, in the same study five stiff wires were also tested and the GlidewireS (Boston Scientific) required the greatest force in the perforation test and the lowest tip bending force, as did the EZ GliderS (Olympus) [8].

A standard guidewire would also have a fairly stiff midshaft to straighten the ureter and facilitate coaxial passage of other devices (e.g. sheaths, stents). It would have a floppy tip on the external end to facilitate atraumatic back-loading of the flexible ureteroscope if needed. The Bard Sensor guidewire (Boston Scientific) is a hybrid wire that combines these components; a hydrophilic distal tip, shift shaft (nitinol core with polytetrafluoroethylene coating), and floppy proximal tip [9]. We typically utilize a 0.035 inch Olympus UltraTrack guidewire as our initial guidewire to cannulate the ureteral orifice and advance up to the level of the renal pelvis. If resistance is encountered, a 5 Fr open-ended catheter is advanced to the level of resistance under fluoroscopic guidance and retrograde pyelography is performed to delineate the ureteral anatomy. A 0.035 inch straight-angle hydrophilic Terumo Glidewire (Terumo Interventional Systems, Somerset, NJ, USA) is then placed through the open-ended catheter and advanced beyond the site of obstruction. For coaxial passage of ureteral access sheaths and large caliber stents and catheters an Amplatz Superstiff in utilized to minimize the risk of wire buckling or kinking (Boston Scientific).

The Orchestra (Coloplast, Humlebaek, Denmark) is a new hydrophilic guidewire that has demonstrated, in an *in vitro* analysis, similar safety performance while providing a stiff shaft and more lubricous coating when compared to Glidewire [10].

In conclusion, each hydrophilic guidewire has particular properties that can be translated into advantages for a specific case; therefore it is important for the endourologist to be attentive to technological advancements and performance reports.

### Torqueable catheters

At times the ability to guide a wire past a point of particular tortuosity may prove beneficial to establish secure guidewire access. One alternative would be to utilize an angled-tip guidewire and a torque device which attaches to the external end of the wire. Rotating the torque device reorients the tip of the wire to direct it towards the anticipated path of the lumen as outlined on retrograde pyelography. Alternative, a variety of torqueable angled catheters (Kumpe catheter, JB-1 catheter, Cobra catheter) can be utilized to help guide the wire in the correct direction.

## Ureteral access sheaths

Ureteral access sheaths (UAS) facilitate expeditious and atraumatic entry and re-entry to the upper collecting system with the flexible ureteroscope, while eliminating the risk of buckling of the endoscope in the bladder. The use of a UAS has been demonstrated to decrease operative time and cost, minimize patient morbidity, and optimize overall success of flexible ureteroscopy [11]. Specifically, a retrospective case series has demonstrated superior stone-free rates in a contemporary series of patients undergoing ureteroscopy with the use of an access sheath compared to no access sheath [12].

The access sheath also protects the upper urinary tract from increased peak intrarenal pressure even with irrigant fluid pressurized to 200 cm$H_2O$, as it allows efflux of irrigant fluid through the sheath and around the ureteroscope, maintaining intrapelvic pressures below 20 cm$H_2O$ [13]. Finally, some authors have suggested that the use of a UAS decreases the risk of endoscope damage [14]. Conversely, UAS insertion has recently been associated with ureteral injuries of various magnitudes [15], endorsing the importance of knowing the characteristics of each UAS available in the market so as to choose the most appropriate one for a particular case.

*In vitro* and randomized clinical studies have demonstrated that the Cook Flexor® sheath (Cook Urological, Bloomington, IN, USA) is superior with regards to ease of placement, instrument passage, and stone extraction [16], is more resistant to both buckling at the ureteral orifice and kinking after removal of the inner dilator [17], and has one of the largest inner diameters in the most common bending positions of straight and 30° bends, which further facilitates stone extraction [18]. Nevertheless, in a recent *in vitro* study, the Navigator HD (Boston Scientific) was found to be the most resistant to buckling and have the most slippery sheath when compared to other new-generation UAS, whereas Cook Flexor sheaths were the least traumatic [19].

New UAS models have been designed, such as Re-Trace® (Coloplast) and Cook Flexor Parallel® (Cook Urological); both can slide over a stiff guidewire placed only at the tip of the inner sheath (outside the sheath shaft). This new design allows for an easy extraction of the inner sheath without taking out the working wire, which, in turn, becomes the safety wire. Additionally, the Cook Flexor®DL (Cook Urological) UAS offers an additional 3 Fr working channel. The extra working channel can be used for irrigation, to deliver contrast, and for introduction of wires and baskets in parallel to the sheath itself.

A 12/14 Fr UAS is the standard size utilized for adults, as studies have demonstrated that this internal diameter optimizes irrigant flow and intrapelvic pressures [20]. Typically a 35 cm long sheath is utilized for women and 45 cm is utilized in men if the goal is to reach the ureteropelvic junction. If the sheath does not go up the ureter, the inner dilator can be used without the outer sheath to dilate the ureter over a superstiff guidewire. If unsuccessful one might utilize a ureteral balloon (see below) through the sheath or place a ureteral stent to passively dilate the ureter.

## Intracorporeal lithotrite

While a number of different endoscopic lithotrites, such as ultrasonic, electrohydraulic, pneumatic, and laser, have been utilized for ureteroscopic lithotripsy, the holmium laser has become established as the standard of care, due to its efficiency, versatility, and safety. *In vitro* analyses have demonstrated that the holmium laser fragments all stone compositions and produces smaller stone fragments than pneumatic, electrohydraulic, and pulsed-dye (Candela) lithotripsy [21]. While electrohydraulic can cause damage even if fired from several millimeters away, holmium laser can be safely activated at a distance of 0.5–1 mm from the ureteral wall without risk of perforation as the energy is effectively absorbed in the fluid medium [22].

Holmium:YAG laser lithotripsy generates a photothermal process that leads to direct absorption of the laser energy by the stone and thermal combustion. It also creates a vaporization bubble that subsequently destabilizes and decomposes the stone [23]. It has been published in clinical trials that the stone-free rates both at the end of the ureteroscopy and 3 months postprocedure were significantly higher for holmium than either electrohydraulic [24] or pneumatic [25] lithotripsy. Currently, dual-pulse-width laser lithotripsy has shown in *in vitro* studies to cause less stone retropulsion with the same stone fragmentation rates [26].

Laser energy is brought to the target (stones) with the aid of laser fibers, which are thin and flexible, the optimal characteristics for passing through the working channel of a flexible ureteroscope. Studies on performance and safety of commercially available holmium laser fibers demonstrated that the Dornier Lightguide 200 was the most likely of small fibers (200–273 mm) to fracture and damage a flexible ureteroscope, while the Lumenis 272 (Coherent) and the Innova Quartz 400 (Gyrus-ACMI) were the most durable in their size class [27].

The 365 μm laser fiber is more durable and results in the best stone fragmentation efficiency [28, 29]. However, the increase in size leads to a decrease in active deflection of the flexible ureteroscope; only 7–16% of maximum deflection (−9 to −19°) is lost with the 200 μm fiber compared to 18–37% (−24 to −45°) of maximum deflection with the 365 μm fiber [30, 31].

Flexxiva® (Boston Scientific) is a newly designed ball-tip laser fiber. Its atraumatic tip is protective of the working channel and has shown reduced insertion forces when compared to standard, flat-tip fibers [32]. Flexxiva passes through a deflected scope without puncturing or tearing the scope coating [32].

Pneumatic lithotripsy has the advantage, especially in areas where resources are limited, of low maintenance and disposable costs. The disadvantages of pneumatic lithotripsy are the increased risk of stone migration and the inability to apply this modality through a flexible ureteroscope.

Electrohydraulic lithotripsy generates a spark which results in plasma expansion at supersonic speed, propagating a hydraulic shock-wave and cavitation bubble. Collapse of the cavitation bubble leads to a second shock-wave, which if asymmetric leads to formation of a liquid jet. Each of these mechanisms results in stone fragmentation [33, 34]. However, the safety of the device is the primary concern, with one series reporting a 3% conversion rate to open surgery due to ureteral perforation in conjunction with a stone-free rate of only 58% at 3 months [35].

## Ureter-occluding devices

A variety of devices have been developed to prevent stone migration during intracorporeal lithotripsy. The Stone Cone (Boston Scientific) consists of concentric coils which act to prevent proximal retropulsion of stone fragments, and it has proved to reduce the incidence of residual stone fragments >3 mm in size [36]. The 2.8 Fr Cook N-Trap is composed of 24 interwoven nitinol wires that has been shown in *ex vivo* pig ureters to prevent the migration of small plastic beads as small as 1.5 mm [37]. Each device is designed to release any larger fragments as the device is withdrawn. It has been demonstrated that the Stone Cone releases the stone with a mean of 0.19 lb of force while the N-Trap releases the stone with a mean of 0.86 lb of force, suggesting a potential safety advantage with the Stone Cone [38]. More recently, the Percsys Accordion has been launched and was proved in an *in vitro* comparative study to be as safe and efficient as the Cook and Boston Scientific counterparts [39].

*In vitro* studies have evaluated a biogel polymer that is delivered using a 3 Fr ureteral catheter above the stone to occlude the more proximal ureter. The triblock polymer of polyethylene oxide is a liquid at low temperatures and turns into a gel at body temperature.[40] Warm irrigation must be utilized during the procedure, then cold saline is instilled to liquefy the polymer at the completion of lithotripsy. Residual polymer dissolves in urine after 2 hours and is expelled [34]. In a recent randomized clinical trial, Rane et al. reported the successful use of a water-soluble polymer (BackStop) to prevent stone migration during semirigid ureteroscopy. The study showed that this polymer was efficient in stabilizing the stone during laser or pneumatic lithotripsy; moreover, no adverse events were associated with its use compared to conventional ureterolithotripsy [41].

Each of these devices and techniques require additional manipulation prior to ureteral lithotripsy, so the benefit of their use should be weighed against the additional risks of perforation in the face of a large ureteral stone. Specifically, their use may be most warranted in situations where pneumatic lithotripsy is planned and the risk of migration is higher, or if there is significant hydroureteronephrosis above the stone, or if there is limited availability of flexible ureteroscopy to retrieve stones that migrate.

## Stone retrieval devices

A stone retrieval device is essential in ureteroscopy. Each device can be evaluated and distinguished by its ability to be visualized during stone manipulation, to provide radial force to open in the ureter, and to capture, retain, or, if necessary, disengage a stone. Alligator or rat-tooth forceps are preferred by some due to their reversible grasp and reusability; however, the large size and weak grasp impact their effectiveness [41].

Nitinol-based baskets are more versatile due to the unique pliability of the wires and to the flexibility that allows full lower pole deflection of a flexible ureteroscope in the majority of cases [42, 43]. *In vitro* studies have shown that the Cook N-Circle 2.2 Fr (Cook Urological) was the most efficient in stone capturing in a ureteral model while the Sacred Heart Halo 1.5 Fr (Sacred Heart Medical, Minneapolis, MN, USA) was most efficient in a calyceal model compared to 12 other baskets [44–46]. If there are stone fragments adherent to the renal papilla, the Cook N-Circle 2.2 Fr basket wires are more pliable and can be distorted with gentle pressure until they embrace and grab the adherent stone.

The Cook N-Compass (Cook Urological), with its webbed configuration, is designed to optimize the retrieval of multiple small (1 mm or less) stone fragments that may result from lithotripsy of a large burden intrarenal stone.

The Bard Dimension basket has a unique lever that extends two wires to "deflect" the cage of the basket. It has been proposed that this facilitates retrieval from stones in hard-to-reach calyces and facilitate stone release if needed [47]. However, other investigators have reported that this affords no advantage for either stone capture or stone release [48]. The Boston Scientific Graspit and Cook NGage are two devices that have coupled the properties of a three-prong grasper with the entrapment capability of a regular tipless nitinol basket. It has been proposed that they provide a better ability to grasp and release the stone [49].

The 1.5 Fr Sacred Heart Halo has been demonstrated to be the most efficient at stone retrieval of smaller fragments and provides superior irrigation compared to the Microvasive Zerotip 1.9 Fr [50]. In addition, it allows rotation of an engaged stone via a rotary wheel on the basket handle, and simultaneous laser lithotripsy, as a 200 μm laser fiber can be passed alongside the Halo basket, a technique that is utilized if a stone is too large for removal down the ureter. The 1.9 Fr Escape nitinol stone retrieval basket (Boston Scientific) offers the same "side by side" approach, preventing retrograde ureteral stone migration [51]. These two devices are of particular interest in cases of entrapped ureteral or renal stones where laser lithotripsy prior to stone capture cannot be accomplished. Recently the Boston Scientific 1.3 Fr Optiflex basket has been released, and this is currently undergoing evaluations.

## Ureteral balloon dilators

Ureteral balloon dilation is utilized in approximately 5% of cases, when the UAS will not advance to the site of pathology due to ureteral stricture, spasm, or a tight ureteral orifice. Ideally a ureteral balloon would dilate to 100% of the expected diameter regardless of any amount of radial constrictive force. An *in vitro* study compared the dynamics of ureteral balloon expansion under varying extrinsic compressive forces and inflation pressures [52] and concluded that at inflation burst pressure, the Cook Ascend AQ (Cook Urological) was the most reliable balloon, achieving and maintaining over 100% of the expected inflation diameter with minimal pressure and a small coefficient of variation. Not evaluated in this study was the new Bard X-force balloon dilator, which is the only balloon rated to 30 atm inflation pressure.

## Flexible ureteroscopes

Current flexible ureteroscopes offer increased lower pole access through exaggerated active deflection compared to older passively deflecting scopes. Some achieve this by incorporating separate dual-lever primary and secondary active deflection that offers increased unidirectional downward deflections of 270° (Gyrus-ACMI DUR-8-Elite, Stryker Flexvision). Other endoscopes provide increased bidirectional primary deflection of up to 270° using one deflection lever (Gyrus-ACMI DUR-D, Olympus URF-P5, Karl Storz Flex-X2, Richard Wolf Viper). In addition, a dual-channel flexible ureteroscope has been developed which affords the opportunity to hold traction on soft tissue while transecting the tissue with a laser, or the ability to hold a stone in a basket while laser ablating through the second channel (Richard Wolf Cobra®). This endoscope offers superior deflection and irrigation characteristics in particular when larger 2.4 Fr accessory instruments are utilized [53].

A comparative study of the fiber-optic flexible ureteroscopes available in market showed that the Wolf Viper (Richard Wolf Endoscopy, Vernon Hills, IL, USA) provides superior irrigant flow, and better visualization through the unique fused quartz bundle compared to glass fiber-optic bundles [54]. Moreover, the Wolf Viper 7.5 Fr was shown to have twofold greater resolution than the other flexible fiber-optic ureteroscopes [55], and *in vitro* evaluations of scope manipulation have demonstrated that the Wolf Viper is superior at accessing all calyces in a hydronephrotic kidney model [56].

Another critical consideration is the durability of the flexible fiber-optic ureteroscope. It was first evaluated by Afane et al. who noted that despite flexible ureteroscopes being highly efficient in diagnosing and treating upper tract abnormalities, they needed to be repaired after only 6–15 uses, mostly due to problems in the deflection unit [57]. Subsequently, a randomized prospective multicenter study demonstrated that the Gyrus-ACMI DUR-8-Elite was the most durable flexible ureteroscope in 2005 [58]. Another randomized clinical study of the next generation of flexible ureteroscopes demonstrated that the Wolf Viper, Olympus URF-P5, and Stryker Flexvision U-500 flexible ureteroscopes appeared comparable with regard to durability, suggesting that some parity has been achieved between manufacturers [59].

Modern digital flexible ureteroscopes (Olympus URF-V, ACMI DUR-D) offer improved ease of handling and visibility as they have eliminated the light cord and improved optical resolution with complementary metal oxide semiconductor (CMOS) technology. Digital scopes employ light-emitting diode (LED) technology, a durable and cheap cool light, putting aside the traditional xenon light, an expensive and less durable heat-generating light source. The absence of optic fibers in the shaft of the flexible scope allows for better deflection and adds simplicity to the instrument, which may lower costs, improve maneuverability, and result in more durability [60]. However, Knudsen and Ferraro reported that the distal lens of a digital ureteroscope appears to be extremely fragile and prone to breakdown, different to what has been previously reported. The authors concluded that to improve reliability and cost-effectiveness refinements of digital scope design are still required [61]. Interestingly, opposite to the above-mentioned findings, a more recent study looked at the performance and durability of two digital scopes, Flex-Xc® (Karl Storz) and URF-Vo (Olympus), and found that the latest models of flexible digital ureteroscopes demonstrated good maneuverability and visibility, less deflection deficiency, and better visual quality when compared to the Wolf Cobra [62]. Additionally, a prospective randomized trial comparing two digital scopes, DUR-D (ACMI/Olympus) and URF-V (Olympus), showed that both had similar failure rates compared with the fiber-optic scopes, while providing better image quality [63].

## Disposable flexible ureteroscopes

A cost-effective technology is available for retrograde access to the upper urinary tract, and it is based on the premise of a single-use flexible endoscope, which eliminates the need for sterilization between cases.

The first design comprised a reusable fiber-optic cable attached to a handle with a deflection lever, a detachable light source, and an irrigation source. For every new case a sterile 8 Fr sheath is snuggly advanced over the fiber-optic shaft, keeping the latter from touching the patient. This sterile sheath contains a 3.3 Fr working channel and is capable of deflecting along with the fiber-optic cable. [64] It was reported by Boylu et al. that this new modality of endoscope has acceptable active tip deflection, field of view, and flow rate compared to six other flexible ureteroscopes on the market [64]; however, it is advised to use this type of disposable ureteroscope for simple clinical cases only, reserving traditional reusable flexible ureteroscopes for more complex cases.

More recently, the Boston Scientific LithoVue® single-use digital flexible ureteroscope (Boston Scientific) was launched. LithoVue reaches 270° deflection in both directions and has image quality comparable to reusable flexible digital scopes [65]. It has been tested in live porcine models and had demonstrated similar performance to the fiber-optic URF-P5 (Olympus) with better visual quality [66].

The concept of the single-use flexible ureteroscope relies on using always a brand new scope for each case, thus avoiding scope repairs, inconsistent performance, reprocessing, and degradation associated with reusable scopes.

## Endo-irrigation systems

The passage of instruments through the working channel of a flexible ureteroscope can significantly decrease irrigant flow and result in poor visualization. Gravity with or without the assistance of pressure-bag compression is commonly utilized. With the use of a UAS, intrarenal pressures can be maintained below 30 $cmH_2O$ even with systems pressurized to 200 $cmH_2O$ [67]. Alternatively, handheld, foot-pedal-controlled, or automated irrigation systems may be utilized.

An automated irrigation/suction system (Endo-FMS Urology, Future Medical Systems USA, Glen Burnie, MD, USA) incorporates an irrigation roller pump with a suction roller pump (functional during rigid ureteroscopy only) to provide continuous flow and controlled pressure. The Peditrol (EMS Medical Systems, Stroud, UK) is a foot-pedal syringe-based irrigation system that functions by two separate one-way valves, one attached to gravity or a pressure bag and the other attached to a 3 ml syringe secured to the Peditrol foot pedal. The Boston Scientific single-action pump is a 10 ml vacuum syringe that has one-way valves that provide automatic refill of the syringe for immediate access to irrigation fluid.

An *in vitro* study evaluated the impact of stone migration with each system as well as the efficiency of irrigation to clear the operative field of blood, as measured by number of pulses and duration of irrigation. The study demonstrated that, of the hand-held devices, the Boston Scientific single-action pump exerted the weakest impulse on a stone, decreasing the likelihood of dislocating the stone during endoscopic surgery [67]. Although pressurized saline bags were not as efficient at clearing the operative field, they did result in less migration than hand-held or foot-pedal devices.

Recently, a pressurized irrigation system that allows concurrent temperature control, FluidSmart® (Thermedx, Solon, OH, USA), was appraised in an *in vitro* study and shown to be a promising pressurized/warmed irrigation strategy [68].

## Future innovations

Future innovations may lead to higher stone-free rates. Investigators are developing iron oxide microparticles that bind to the calcium component of stones and provide the opportunity for expeditious extraction with a magnet-tipped retrieval device [69]. Alternatively, future innovations may lead to safer procedures. The addition of isoproteronol (a β-1,3-adrenoreceptor stimulant) to the irrigating solution during ureteroscopy relaxes the ureteral smooth muscle, leading to lower intrarenal pressures and may facilitate the passage of fragments, debris, or clots [70].

As technology advances, the scientific world witnesses the introduction of new minimally invasive treatment modalities for a broad scope of diseases. Flexible ureteroscopy is a good example of this, and it has become the standard of treatment for almost any kind of kidney stone. However, it demands training and practice in order to outrun the learning curve and acquire coordinated hand skills. Recently a robotic platform has been designed for flexible ureteroscopy to improve ergonomics, learning, and treatment outcome. To date, new studies have demonstrated encouraging results for robotic flexible ureteroscopy [71, 72].

These are a few futuristic concepts that may lead to better outcomes for the patient and facilitate the procedure for the endourologist. Driven by innovation, endourology will remain a dynamic field, with evolving improvements towards the best clinical practice.

# Access to the Ureter: Rigid Ureteroscopy

*Jose De La Cerda, III & Timothy Y. Tseng*

*Department of Urology, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA*

## Introduction

With ongoing technological advances in both minimally invasive and noninvasive techniques, there are increasing options for the evaluation and treatment of ureteral pathology. In particular, advances in the miniaturization and optics of flexible endoscopic equipment have dramatically improved the success of endoscopic treatment for proximal ureteral and renal collecting system pathology. Despite these innovations, rigid ureteroscopy demonstrates distinct advantages and retains a key role in the treatment of upper urinary tract pathology.

## Indications for semirigid and rigid ureteroscopy

With larger working channels that allow for enhanced irrigation and passage of larger endoscopic instruments such as biopsy forceps, rigid and semirigid ureteroscopes are the favored approach for access to the distal ureter and treatment of all distal ureteral conditions including ureteral calculi, tumors, and strictures [1, 2]. Classically, the ureter is divided into three segments: the mid ureter overlying the sacrum, and the proximal and distal ureter superior and inferior to the sacrum [3, 4]. In practice, rigid ureteroscopy was occasionally limited by the natural angulation of the ureter over the iliac vessels [5]. Semirigid ureteroscopes, which contain fiber-optic bundles rather than a solid lens, can overcome this limitation by affording a small degree of shaft flexion over the iliac vessels.

For distal ureteral calculi, rigid and semirigid ureteroscopy demonstrate superior stone-free rates compared to shock-wave lithotripsy (SWL) (90–97% vs. 75%, respectively) [2]. Rigid and semirigid ureteroscopy also appear to have stone-free rates comparable to endoscopy with flexible ureteroscopes only (90–97% vs. 93–97%, respectively) [2]. Recent data have also demonstrated that rigid and semirigid ureteroscopy can be used to successfully treat proximal ureteral stones [6]. Although flexible ureteroscopy demonstrates the highest stone-free rate for treating stones at any location in the ureter (95%), rigid and semirigid ureteroscopy demonstrate stone-free rates that are only somewhat lower (85–92%) [6]. This is in contrast to SWL, which demonstrates a stone-free rate for stones at any ureteral location of only 69% [1]. These data emphasize the fact that rigid and semirigid ureteroscopy can be used successfully throughout the ureter and that their use should not be dogmatically limited to the distal ureter. Because of their advantages and relative ease of use, rigid and semirigid ureteroscopy can be the initial modality for accessing the ureter as far proximally as the anatomy safely permits.

## Preoperative considerations

As with any surgical patient, a thorough history and physical examination are key to identifying conditions that may lead to potential intraoperative and perioperative complications [7]. The American Society of Anesthesiologists recommends against the routine ordering of preoperative laboratory studies in patients without risk factors, although this remains controversial [8]. According to guidelines from the American Urological Association, a complete blood count would not be necessary for ureteroscopy as the risk of hemorrhage is very low. Serum creatinine and electrolytes are

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

necessary if there is suspicion for decreased renal function [1]. With any planned urinary tract instrumentation, preoperative urinalysis and culture should be obtained and culture-specific antibiotics should be prescribed to attempt to sterilize the urine prior to the procedure [1, 9]. In the absence of clinical indications, coagulation studies do not need to be routinely obtained prior to the endoscopic management of stone disease [1, 8]. Indeed, ureteroscopy with holmium:YAG lithotripsy has been shown to be safe and effective in patients on full therapeutic antiplatelet and anticoagulant therapy [10].

Although placing a ureteral stent prior to ureteroscopy to allow passive dilation of the ureter has been shown to lead to decreased operative time and higher stone-free rates [11–13], this is not recommended as a routine practice due to the added costs and diminished quality of life associated with stenting [1].

## Patient positioning

Two positions have been described for ureteroscopy: dorsal lithotomy and modified dorsal lithotomy in which the ipsilateral leg of the ureter being examined is slightly extended and abducted [14] (see Figure 44.1). Immediately after induction of anesthesia, the patient can be positioned according to surgeon preference. Extension of the leg and abduction of the hip minimizes the angle of the ureter over the psoas muscle and therefore facilitates the passage of the rigid or semirigid ureteroscope into the ureteral orifice and proximally into the ureter [15]. In a study by Korkes et al. the modified dorsal lithotomy position resulted in a significant decrease in operative time when compared to the dorsal lithotomy position [14]. Complication and success rates remained similar between both positions.

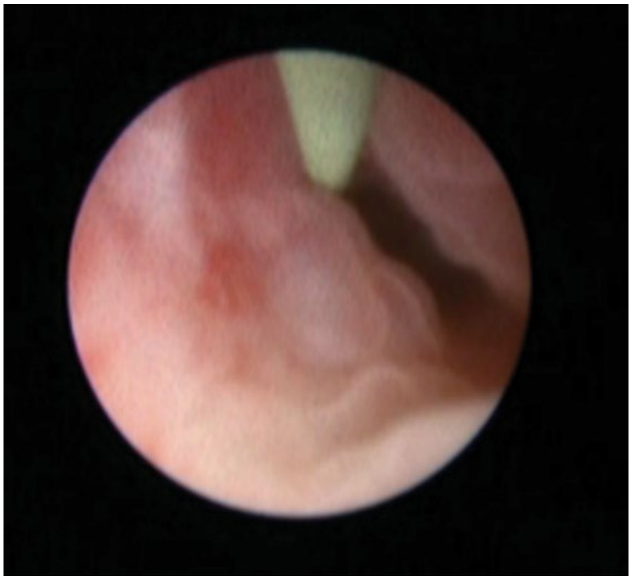

**Figure 44.1** Accessing the ureter with a single wire in place. The safety wire can be tented upwards to facilitate access of the ureter by the rigid ureteroscope inferiorly.

## Equipment for rigid and semirigid ureteroscopy

### Instruments

Although not absolutely required, a rigid or flexible cystoscope is frequently used to place guidewires to facilitate ureteroscopy. Less commonly, guidewires can be placed using the ureteroscope itself. On occasion, however, difficulties associated with an enlarged prostate or edema of the ureter may make cannulation of the ureteral orifice difficult without the wider view of the cystoscope. Difficulties encountered in bypassing an impacted stone can also frequently be overcome by using a rigid cystoscope with a sheath larger than 17 Fr that can accommodate an open-ended ureteral catheter through which multiple wire types can be exchanged prior to placement of the ureteroscope within the ureter.

Rigid and semirigid ureteroscopes are available in a variety of sizes that range from 4.5 to 12 Fr and have working channels that range from 2.3 to 6.4 Fr [16]. There are typically one or two working channels. With two working channels, a constant flow of irrigation can be maintained despite placement of working elements such as laser fibers or stone retrieval baskets.

### Guidewires

Initially developed for vascular procedures, guidewires have become an essential part of upper urinary tract endoscopy [17]. Guidewires are often used as the first means of accessing the ureter and the collecting system. A number of different guidewires are available with different core designs, diameters, and coatings. Selection of a particular guidewire depends upon its intended use.

Guidewires typically have soft, flexible tips to prevent tissue damage [18]. They are generally made up of two components: an outer polytetrafluoroethylene (PTFE) coating, which provides for a hydrophobic surface that is more easily handled, and an inner steel core which determines the rigidity and flexibility of the wire [18]. Nitinol (nickel-titanium) can be substituted for the inner core and allows resistance to kinking as opposed to the stainless steel core wire which can be permanently bent rather easily [17, 19]. Guidewires range in a diameter from 0.018 to 0.038 inches, with the majority of wires used in ureteroscopy being 0.035 and 0.038 inches. Larger-diameter wires provide increased stiffness at the potential cost of impaired irrigation flow should the wires need to be passed through a flexible ureteroscope. With the multiple larger diameter working channels of rigid and semirigid ureteroscopes, decreased flow is not typically a concern when flexible ureteroscopy is not contemplated.

Standard stainless steel/PTFE wires and nitinol/PTFE wires are well suited for obtaining and maintaining ureteral access during uncomplicated ureteroscopy. Hydrophilic wires have low-friction characteristics that are useful for negotiating beyond a ureteral obstruction such as that due to an impacted stone or a ureteral stricture. As hydrophilic wires typically lack the stiffness and friction required for easy handling, they are typically not used as safety wires and should be exchanged for a standard wire once an obstruction has been bypassed. Stiffer wires (Amplatz style) are useful for preventing buckling or kinking of wires while placing dilators and access sheaths [20].

### Irrigation devices

Pressure irrigation systems are necessary for visualization in the upper urinary tract as gravity irrigation is typically insufficient to distend the ureter and collecting system through the small working channels of ureteroscopes. Pressure irrigation also helps to clear the endoscopic field of stone fragments, blood, and debris [21]. Due to the risk of systemic absorption from pressure irrigation and/or ureteral perforation, normal saline is the irrigant of choice to prevent electrolyte disturbances [22, 23]

Commonly used commercial irrigation devices are syringe-style pumps (Single Action Pumping System, Boston Scientific), bulb-style pumps (Pathfinder, Utah Medical), and hands-free foot pumps (Flo-Assist, Nortech). Each of these systems provides pressure irrigation in a pulsatile manner. Bulb pumping appears to be associated with less operator hand fatigue compared to syringe irrigation while syringe irrigation appears to allow finer titration of irrigation flow [24]. All three systems have the disadvantage of requiring an assistant to provide the pressure irrigation. Furthermore, the quality of irrigation is dependent upon operator technique and operator fatigue.

Pressure irrigation can also be achieved with a simple pressure bag or a pressure irrigation system such as a Level 1 Normoflo irrigator (Smiths Medical). Such irrigation systems have the advantage of maintaining constant pressure and continuous flow without the need for an assistant. When such systems are used, the target irrigation pressure is 150 mmHg. Once the target pressure has been reached within the collecting system, a standing column of fluid is theoretically established such that retropulsion of stone fragments is diminished relative to manual, pulsatile irrigation. In addition, manual irrigation, in which pressures are not regulated, can generate potentially greater irrigation pressures that could lead to increased risk of sepsis in infected systems. It is also important to use warm irrigation to prevent hypothermia during prolonged endoscopic cases. The Level 1 irrigator has the added benefit of warming the irrigant as it passes through the device.

### Fluoroscopy

Intraoperative fluoroscopy is necessary to confirm appropriate placement of guidewires and stents. Fluoroscopy is also useful for mapping the upper urinary tract with pyelography, identifying calculi, and assessing progress during the procedure [25]. Fluoroscopy can be accomplished with a standard C-arm or a fixed fluoroscopy table. With the advent of video monitors, most urinary tract endoscopy is now performed in the standing position. A C-arm, which has its radiation source below the table, scatters radiation predominantly toward the floor, thereby reducing a standing surgeon's head and upper torso radiation exposure relative to a fixed fluoroscopy table that involves a radiation source above the table [26]. Regardless, personal protection including lead aprons, thyroid shields, and leaded eyewear should be worn when in close proximity to the fluoroscopy unit.

## Accessing the ureter

### Cystoscopy and placement of a safety wire

A rigid or flexible cystoscope is typically used for the initial placement of a safety wire into the ureter. Immediately prior to guidewire placement, a thorough assessment of the bladder for abnormal pathology should be done. Safety wire placement is recommended to allow for rapid re-access to the ureter or stent placement, particularly in the event of an iatrogenic ureteral injury such as ureteral perforation necessitating early termination of the procedure [1, 2, 27].

For placement of a safety guidewire, a 21 or 22 Fr rigid cystoscope with a 30° lens is placed as close to the ureteral orifice as possible to minimize deflection of the wire over the prostate and bladder neck. The cystoscope may be turned up to 180° to further minimize the angle of approach to the ureteral orifice. A 5 or 6 Fr open-ended ureteral catheter can be employed to further direct the floppy tip of the wire into the ureteral orifice. With an open-ended ureteral catheter, a retrograde pyelogram can be performed to identify the course of the ureter and any anatomic abnormalities such as tortuosities, stones, or strictures [28]. A retrograde pyelogram is not always necessary if a guidewire passes easily and coils uneventfully in the renal pelvis. If tortuosities or obstructing stones are encountered, a hydrophilic wire with an angled tip may be negotiated beyond this area and exchanged for a standard safety wire after advancing the open-ended ureteral catheter beyond the difficult area [29]. Should a safety wire not be able to be placed beyond a tortuosity or impacted stone, the wire may be left distally and a rigid ureteroscope passed into the ureter for direct visualization of wire placement and possible treatment of the obstruction to allow adequate safety wire placement. If purulent drainage from the ureter is noted after wire placement or cannulation of the ureter, the procedure should be aborted to prevent potentially serious infectious complications. A urine culture should be obtained and drainage of the renal unit with either a stent or nephrostomy tube should be performed [1]. The patient should subsequently be treated with culture-specific antibiotics and the procedure performed at a later date.

If the patient has been previously stented and the stent does not appear encrusted, the stent may be withdrawn and the safety wire passed through the stent. Should significant edema of the ureteral orifice be encountered, placement of a safety wire alongside the existing stent prior to its removal would be recommended to avoid the situation in which access to the ureter is lost and the ureter cannot be recannulated.

### Ureteroscope insertion

After appropriate placement of a safety guidewire, the bladder should be drained to reduce compression and angulation of the intramural ureter and to prevent over-distension of the bladder during ureteroscopy [28]. A rigid or semirigid ureteroscope may then be passed into the ureteral orifice. Typically, the ureteroscope is passed underneath the safety wire as this maneuver allows the ureteral orifice to be tented open. Occasionally, the ureteral orifice is too narrow to permit passage of the ureteroscope easily. In this situation, a second guidewire may be placed through the working channel of the ureteroscope into the ureter (see Figure 44.2). The ureteroscope is then advanced between the two wires, safely and gently dilating the ureteral orifice [28] (see Video 44.1)

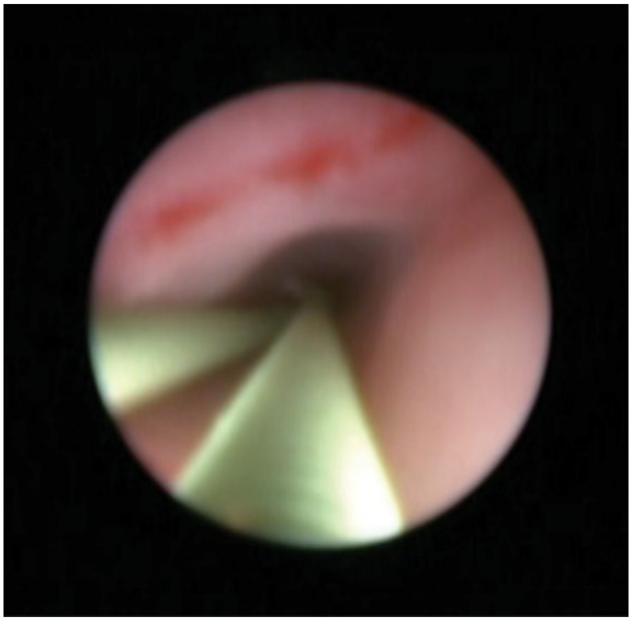

**Figure 44.2** Accessing the ureter with two wires in place. After previously placing a safety wire, a second wire can be placed through the working channel of the ureteroscope into the ureter. The ureteroscope can then be gently advanced between the two wires.

### Ureteral dilation

It is estimated that a difficult ureter will be encountered in 8–11% of patients who are undergoing ureteroscopy without prior stent placement [30]. If the ureteroscope does not pass easily between two wires, a stent may be placed and the procedure aborted to allow passive dilation of the ureter. Alternatively, a tight ureteral orifice and/or ureteral stricture can be dilated rapidly with a 5 mm balloon. The balloon dilator is passed over the safety wire and guided into a position where the balloon markers are above and below the area of narrowing. This can be done through the cystoscope or over a wire under fluoroscopic guidance only. The balloon is then inflated with contrast and the loss of "waisting" at the stricture is visualized fluoroscopically. A retrospective review of ureteral dilation with an 18 Fr balloon by Kuntz et al. demonstrated a 95% success rate for completion of ureteroscopy in a single stage with a low overall complication rate of 8% and a ureteral stricture rate of only 0.7% [31]. Another alternative is the use of coaxial ureteral dilators placed over a wire.

## Altered anatomy

On occasion, anatomical variants are encountered that may make ureteroscopy more challenging. These variants may be congenital, the result of prior treatment, or acute reaction to stone disease and typically involve the ureteral orifice.

### Ureterocele

A ureterocele may be found incidentally during attempted ureteroscopy, frequently in the setting of an obstructing ureterovesical junction calculus. Due to the pinpoint opening of most ureteroceles, balloon dilation or incision either with a cold knife or holmium laser may be required to gain access to the ureter. This is typically done after placing a safety wire to ensure that access to the ureter is not lost after incision. When incising, a low transverse horizontal incision is preferred to prevent subsequent vesicoureteral reflux [32, 33].

### Ureteral reimplantation

Ureteral reimplantation is often performed for the treatment of pediatric vesicoureteral reflux, ureteral stricture disease, and ureteral trauma. Such procedures have the potential to significantly alter trigonal anatomy making endoscopic procedures more challenging. With the Glenn–Anderson ureteral reimplant technique, the ureteral orifice is advanced distally toward the bladder neck [34]. This technique is associated with relative success in obtaining subsequent ureteroscopic access [35]. Of particular concern is the Cohen cross trigonal technique in which the ureteral orifice is relocated to the contralateral side of the trigone and results in an acute angle of approach to the ureteral orifice from the bladder neck [36]. The ureteral orifice in this case can be cannulated with an angled-tip hydrophilic guidewire and open-ended ureteral catheter. Once the open-ended catheter is passed beyond the distal ureter, the hydrophilic wire is exchanged for an extra-stiff wire in order to straighten out the distal ureteral tortuosity [37]. Even if access to the ureter is achieved, ureteroscopy for calculus disease may still be unsuccessful as stone fragments may be unable to pass through the tunneled portion of the ureter [35]. When ureteral access is unable to be achieved, a percutaneous antegrade approach may be necessary.

### Urinary diversion

Urinary diversion poses significant problems for ureteroscopy. These difficulties stem primarily from difficulty locating the ureteroenteric anastomoses [38]. For patients with neobladders or continent catheterizable reservoirs, the redundancy of the reservoir and the presence of an afferent limb typically preclude identification of the ureteroenteric anastomoses. Ileal conduit urinary diversions are somewhat easier to negotiate, with the ureteral orifices being identified at a conduit's most proximal point. Although rigid cystoscopy can be performed with a urinary diversion to place access wires, the additional degrees of movement afforded by flexible cystoscopes or flexible ureteroscopes are useful for identifying and accessing the ureteroenteric anastomoses [38]. Intravenous dyes such as fluorescein, indigo carmine, and methylene blue are also useful in identifying ureteroenteric anastomoses. However, these dyes may be less effective in the setting of an obstructive pathology for which ureteroscopy is being undertaken. Even when ureteral access is achieved, passage of a rigid ureteroscope through the tortuous course created by the urinary diversion is frequently not feasible and retrograde ureteroscopy with a flexible ureteroscope or antegrade ureteroscopy is necessary.

### Stone impaction at the ureterovesical junction

Occasionally, an obstructing stone at the ureterovesical junction can obscure the ureteral orifice and/or prevent placement of a safety wire. The ureterovesical junction and the intramural ureter can also present difficulties in fragmentation of a stone due to the decreased ability to distend this segment with pressure irrigation. If the stone is visible, an attempt to dislodge the stone proximally into a more dilated area of the ureter may be made with the rigid ureteroscope. If this is unsuccessful, laser fragmentation can be performed until the stone can be dislodged. If the ureteral orifice and stone cannot be visualized due to reactive edema, the laser fiber can be used to probe the expected location of the ureteral orifice overlying the calculus bulge. Where the hard calculus can be appreciated in this manner, an incision with the laser can be made to reveal the stone. In all situations, a safety wire should be placed as soon as the stone is dislodged proximally.

## Conclusions

Due to technical advantages unique to rigid ureteroscopy, rigid and semirigid ureteroscopy continue to be integral to the treatment of ureteral pathology, particularly in the distal ureter. While more proximal ureteral conditions may be more successfully treated with flexible ureteroscopy overall, rigid ureteroscopy is not precluded from the proximal ureter. Rigid ureteroscopy may be performed in the proximal ureter as long as the anatomy safely permits. Rigid ureteroscopy should therefore always be considered as complementary to flexible ureteroscopic techniques.

# Access to the Ureter: Flexible Ureteroscopy

*Ojas Shah & Mark V. Silva*

*Department of Urology, Columbia University Irving Medical Center, Columbia University College of Physicians and Surgeons, New York, NY, USA*

## Introduction

Retrograde flexible ureteroscopy (URS) is a widely utilized technique for evaluation and treatment of upper urinary tract pathology, both benign and malignant. Technologic improvements (e.g. smaller-caliber ureteroscopes, greater active deflection) have expanded the role of flexible URS for the management of these processes, including urolithiasis, ureteral stricture disease, and upper tract urothelial or transitional cell carcinoma (TCC). Obtaining ureteral access for flexible URS is typically straightforward, but can be challenging depending on anatomic and disease factors.

In this chapter, we review the preoperative evaluation of patients undergoing flexible URS, preparation of the operating room, and techniques for standard and difficult access. We also review the role and technique for ureteral access sheath (UAS) placement to enable rapid and safe re-entry into the ureter, particularly in the management of stone disease.

## Preoperative evaluation

A thorough history and physical examination should be performed preoperatively. History details that may illuminate an increased risk of difficult access should be elicited. Advance knowledge of these risk factors allows for preoperative planning as well as appropriate counseling of patients regarding risks and the possibility of failed access.

Specific aspects of the past medical history should be emphasized. History of benign prostatic hyperplasia and/or bladder outlet obstruction should be elicited. A large occlusive prostate may impede bladder access and, if friable, may impair visualization secondary to bleeding. A large intravesical median lobe may obscure visualization of one or both ureteral orifices. Chronic bladder outlet obstruction may also cause bladder trabeculations or diverticula, which may distort intravesical anatomy and hinder the identification of the orifices. A history of pelvic or retroperitoneal radiation, or trauma, may increase the likelihood of scar tissue formation, leading to tissue or anatomic distortion. Additionally, history of prior abdominal or pelvic radiation can increase the risk for ureteral stricture formation following ureteroscopic intervention. Large abdominal masses (e.g. abdominal aortic aneurysms, or colorectal, uterine, or ovarian pathology) should be noted as they may cause extrinsic compression of the ureter and/or deviation from its normal course. Patients with retroperitoneal fibrosis, which may be secondary to numerous processes (e.g. trauma, medication-related, idiopathic), may also have narrowing of the ureter.

Surgical history pertaining to the urinary tract should be reviewed. Prior open or endoscopic interventions may increase the risk of ureteral stricture disease and thus make gaining access more difficult. Prior surgery may alter anatomy, including ureteral reimplantation. Reimplantation may also convey risk of vesicoureteral anastomotic stricture or reflux. Review of prior operative reports may guide access planning regarding location of the new orifice. Prior urinary diversion surgery similarly requires ureteral reimplantation, which can make a retrograde approach technically challenging and has a potential risk of ureterointestinal anastomotic stricture. Finally, prior abdominopelvic (e.g. colorectal surgery, hysterectomy/salpingo-oophorectomy) or retroperitoneal surgery (e.g. abdominal aortic aneurysm repair, retroperitoneal lymph node dissection) can lead to stricture disease from injury to or devascularization of the ureter.

Other pertinent details of the patient history include use of anticoagulants or antiplatelet agents. Often these agents can be stopped in consultation with a cardiologist or internist; however, in certain instances patients cannot safely stop these medications and the procedure should be performed as atraumatically as possible. Ureteral dilation techniques should be avoided when operating on patients who are actively anticoagulated. If there is difficulty with access to the ureter, a ureteral stent should be placed to allow for passive dilation prior to definitive treatment. There is evidence that ureteroscopic interventions in patients taking these agents are safe, particularly in the management of stone disease [1–3].

Another important detail of the history is whether a patient demonstrates signs or symptoms of urinary tract infection, or risk factors for colonization of the urinary tract. Patients should be treated to clear an acute infection prior to surgery. Those with colonization should be placed on culture-specific antibiotics prior to surgery to minimize risk of urosepsis with instrumentation.

Informed consent is necessary prior to proceeding to the operating room. Risks and benefits of the proposed surgery should be discussed with the patient preoperatively; these include, but are not limited to, bleeding, infection, injury to the kidney, ureter, and adjacent structures, and ureteral stricture. Patients should be informed of the risk of failed access and the possible need for ureteral stent placement with abortion of the procedure and/or percutaneous nephrostomy tube placement. The more thoroughly patients are counseled preoperatively, the greater trust will persist postoperatively if these situations occur, and subsequent counseling of the patient will be facilitated.

## Preparation of the operating room

Prior to flexible URS, the operating room staff should confirm that all potential instruments and disposable equipment are available, and the surgeon should confirm that this equipment is correct (Table 45.1). The steps of the procedure should be anticipated and the scrub table organized to ensure a smooth succession of events. Additional equipment for difficult access cases may also be required at the discretion of the surgeon (Table 45.1) and should be readily available. If access fails, the patient may require a percutaneous approach or nephrostomy tube, which can be placed by the urologist or interventional radiologist.

Balloon dilators are useful for accessing anatomically tight or strictured segments of ureter. Dimensions of available standard ureteral balloon dilators vary by manufacturer and include balloon lengths of 4–10 cm, inflated balloon diameters of 12–18 Fr (4–6 mm), and dilation pressures up to 30 atm. We typically use 4, 6, or 10 cm dilators with 12–15 Fr balloons inflated to 12 atm under fluoroscopic guidance ideally until no significant "waisting" is noted.

**Table 45.1** Equipment for standard and difficult ureteral access for flexible URS.

| Type of access | Equipment |
|---|---|
| Standard access | Rigid cystoscope (30 and 70° lens) with light cord, camera, and irrigation fluid (Albarran bridge if desired)<br>Nitinol guidewires: 0.035 or 0.038 inch (hybrid guidewire if desired – polytetrafluoroethylene [PTFE]:nitinol with hydrophilic tip); at least two wires (working and safety)<br>Dual-lumen or coaxial catheter<br>Contrast medium (50:50 ratio with saline) for retrograde pyelography with syringe for injection<br>If retrograde pyelogram needed before access to upper tract performed → 5 or 6 Fr open-ended catheter or cone-tip catheter<br>UAS at the discretion of the surgeon<br>Flexible ureteroscope (tested to ensure clear lens and adequate deflection)<br>Ureteral stent (double-J or pigtail) with different calibers and lengths (or multi-length) |
| Difficult access | Flexible cystoscope<br>Semirigid ureteroscope<br>Angiographic catheters with an angled tip<br>Balloon dilators<br>Serial dilators<br>Angled-tip and straight hydrophilic guidewires (with torque device if needed)<br>Various sizes of wire (e.g. 0.025 inch) |

Fluoroscopy (C-arm or table) is required to guide positioning of wires, catheters, and UAS, and to enable retrograde pyelography. Placement of the flexible ureteroscope can be performed with fluoroscopic guidance over the working guidewire up to the level of disease, e.g. stone or stricture, or can be performed under direct vision. Fluoroscopy is also useful for identification of radiopaque stones and following the fragmentation of a stone during laser lithotripsy. The surgeon should confirm that fluoroscopy is correctly positioned and can be easily manipulated prior to surgery.

## Standard retrograde access for flexible ureteroscopy

Depending on institutional protocol, the surgical site (i.e. side for URS) should be marked by the operating surgeon. A time out should also be used that confirms all safety mechanisms are in place and all operating room staff are in agreement with the proposed procedure.

The type of anesthesia will depend on a detailed conversation between the anesthesiologist, surgeon, and patient, and may be influenced by numerous factors (e.g. cardiopulmonary status of the patient, need for apnea during the procedure, patient preference).

The patient is positioned in the dorsal lithotomy position, and prepared and draped in standard sterile fashion. A single dose of prophylactic antibiotic is administered prior to the procedure if the preoperative urine culture is negative. If the patient has a positive preoperative urine culture, they should be treated with a full course of culture-specific antibiotics prior to intervention. Sequential compression devices should be placed on the patient's lower extremities prior to induction of anesthesia whenever used. Alternatively, deep venous thrombosis prophylaxis can be given with subcutaneous heparin or low-molecular-weight heparin.

The bladder is initially entered with a rigid cystoscope. After cystoscopic evaluation of the bladder, the relevant ureteral orifice is identified and cannulated with a guidewire. The guidewire may advance through the end of the rigid cystoscope directly into the orifice, or a 5 Fr open-ended catheter may be required to provide the correct angle for intubation of the orifice. Keeping the camera stationary, the scope can be rotated to change the angle at which the wire advances. When advancing the wire into the orifice, it is important to ensure the end of the cystoscope sits directly at the orifice to prevent buckling or curling of the wire in the bladder. We prefer to use a 0.035 or 0.038 inch × 150 cm hybrid guidewire because its flexible, hydrophilic tip minimizes trauma to the upper urinary tract, it allows easy manipulation around upper urinary tract stones and obstruction, it is kink-resistant, and it has sufficient rigidity to act as a working wire. The wire is advanced gently under fluoroscopic guidance into the kidney (Figure 45.1), minimizing trauma to the collecting system which can lead to mucosal bleeding and obscure visualization. This is particularly important when URS is being performed for evaluation of upper tract TCC as wire trauma may confound evaluation of TCC or carcinoma *in situ*. Also, patients who are anticoagulated or have a bleeding diathesis may have significant bleeding from wire trauma; thus extra caution is necessary in these patients.

If the wire does not advance easily, a retrograde pyelogram should be performed with an open-ended catheter (or with the use of a dual-lumen catheter placed over the initial guidewire) to delineate the ureteral anatomy (e.g. evaluate for presence of ureteral tortuosity, narrowing/stricture, or obstruction). Methods of addressing an inability to advance the initial wire are discussed below.

With the first wire in the correct position, the bladder is emptied through the cystoscope (side port or sheath) to maximize the likelihood of successful passage of a catheter and/or ureteroscope through the intramural ureter. At this time, we typically recommend placement of a second wire as a safety wire. A safety wire allows for ureteral stent placement at any time should there be iatrogenic injury or an inability to proceed. It will also prevent loss of access to the upper urinary tract during the surgery. A dual-lumen or coaxial catheter can be placed over the initial wire into the distal ureter under fluoroscopic guidance and the second wire is advanced alongside the first wire to the renal pelvis (Figure 45.2). A retrograde pyelogram can be performed through the dual-lumen catheter prior to second wire placement if it has not been performed earlier. Alternatively, a second wire can also be placed under direct vision through the

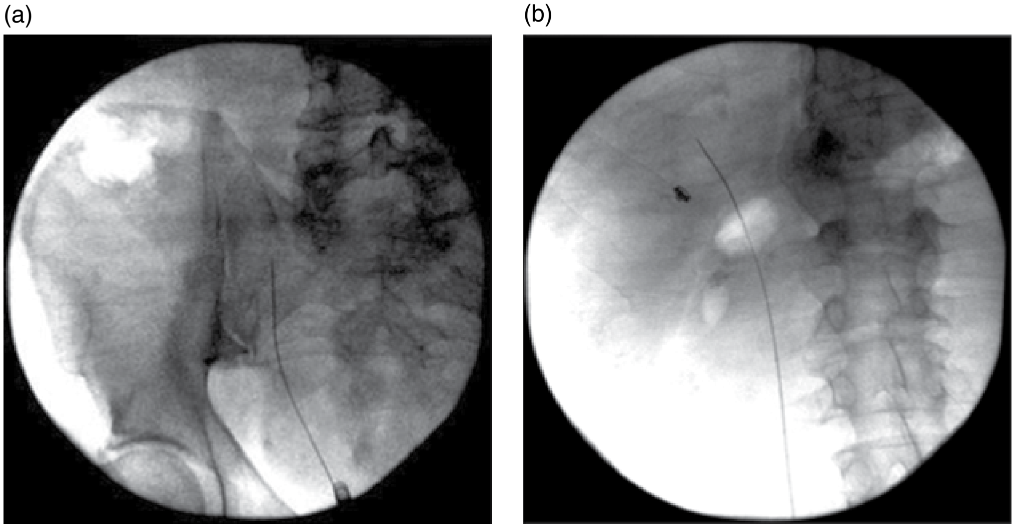

**Figure 45.1** Guidewire advanced to (a) mid ureter and (b) level of kidney.

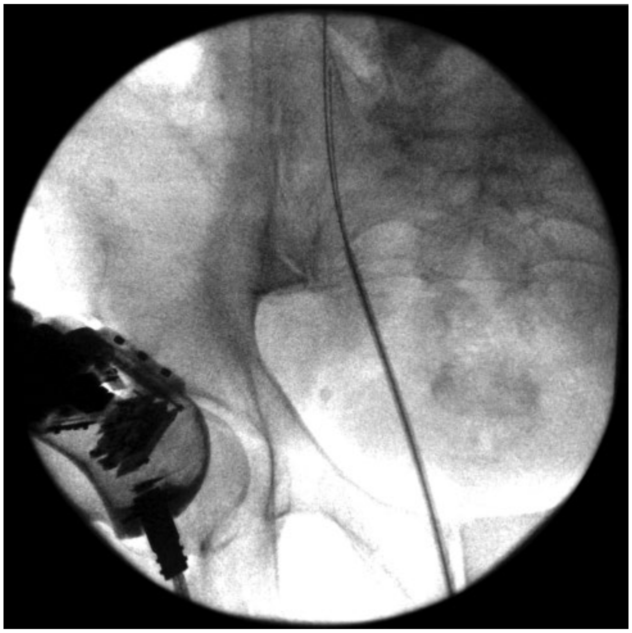

**Figure 45.2** Dual-lumen catheter with two wires advanced.

cystoscope adjacent to the first wire. The benefit of using a dual-lumen 10 Fr catheter or 8/10 Fr coaxial catheter is that either will gently dilate the distal ureter, allowing for easier passage of the flexible ureteroscope.

After the second wire is placed, the dual-lumen catheter is removed and one wire is secured to the drape as a safety wire. The safety wire should be secured away from the immediate surgical field to minimize risk of dislodgment. At this time, the flexible ureteroscope is placed over the working wire and advanced to the level of interest under fluoroscopic guidance.

## Difficult retrograde access for flexible ureteroscopy

Certain situations can confound efforts to obtain ureteral access. Below we discuss methods of troubleshooting these scenarios.

### Ureteral orifice(s) cannot be visualized

There are various reasons why ureteral orifices may not be readily visible on cystoscopic evaluation: distorted anatomy (e.g. bladder trabeculations, mucosal edema, neoplasm), obscured anatomy (e.g. intravesical median lobe), congenital anomalies (e.g. ureteral ectopia), or prior surgery (e.g. ureteral reimplantation, resection). If there is anatomic distortion, an ampule of indigo carmine or methylene blue can be administered intravenously and efflux of dye can be sought. It is important that patients are well hydrated, have adequate renal function, and do not have significant obstruction of the ipsilateral kidney to ensure the dye is rapidly excreted. Intravenous furosemide can be concomitantly administered to expedite excretion from the kidneys. If there is obscured anatomy from a large median lobe, a rigid cystoscope with a 70° lens may enable identification of the orifice. A flexible cystoscope can also be utilized to identify the orifice beneath the lobe and in patients with a very high-riding bladder neck, which prohibits bladder access with a rigid scope. Accessing the orifices with flexible cystoscopy can be technically challenging as irrigant flow and visibility are inferior to those with a rigid scope, and achieving the correct angle for access of the orifice may be difficult. Additionally, the use of an Albarran deflecting bridge or an angled-tip angiographic catheter (e.g. 5 Fr Berenstein catheter) can help deflect guidewires into a ureteral orifice that is at an acute angle or distorted secondary to bladder and prostate anatomy.

If the orifices cannot be found, there should be consideration of congenital anomalies or prior surgical history that may have altered their position. Preoperative imaging can be helpful in delineating upper tract anatomy, including ectopic ureters; urographic imaging is particularly helpful. Clinical history may reveal the possibility of variant or altered anatomy, e.g. history of vesicoureteral reflux disease, incontinence, or chronic pyelonephritis. Review of prior operative reports may provide guidance regarding location of ureteral orifices after ureteral reimplantation.

### Guidewire will not advance through the ureteral orifice

The tip of the cystoscope should be placed immediately at the ureteral orifice to prevent kinking of the wire. A 5 Fr open-ended catheter can be placed through the cystoscope and used as a guide and/or support for the wire, creating the desired angle for access and preventing kinking. An angiographic catheter can also be used for this purpose. Use of an open-ended catheter also allows for retrograde pyelography; the catheter can be placed at the orifice and contrast injected to determine if there is patency of the orifice and/or distal ureter. With the open-ended catheter at the orifice, either a straight or angled-tip guidewire (nitinol or hydrophilic) can be gently advanced and manipulated. If there is concern for a stricture at the orifice or an impacted stone, a rigid ureteroscope can be used to directly access the orifice and wire placement under vision can be attempted. If there is an impacted stone, it can be treated to expose and access the proximal ureteral lumen and enable wire placement; however, without a safety wire this should be done with great care. If wire access cannot be achieved and there is clinically significant obstruction, the procedure should be aborted and a percutaneous nephrostomy tube placement should be performed.

### Guidewire will not advance through the ureter to the kidney

If the wire has successfully accessed the ureteral orifice but will not advance past a level of the ureter, an open-ended catheter should be placed over the wire and a retrograde pyelogram performed to ensure there is no stricture, ureteral injury/false passage, obstructing lesion or stone, or severe tortuosity/J-hooking. This can also be performed with a dual-lumen catheter which can be advanced over the guidewire that has already been placed. If the open-ended catheter will not easily advance over the wire, it is possible that the wire has been placed submucosally, and it should be withdrawn and replaced into the true lumen. If there is a transition point for obstruction or severe tortuosity, the open-ended catheter can be placed to that level to prevent buckling of the wire as it is advanced. An angled-tip hydrophilic guidewire can be useful if there is a severe angle to negotiate. Surgeon experience is critical to understanding how much pressure can be safely applied while advancing the wire. If there is obstruction and concern for a pinpoint stricture, an experienced surgeon may place the ureteroscope over the wire to the level of interest and then attempt to advance the wire under vision. Also, if there is a severely impacted stone and inability to obtain proximal access with a wire, an experienced endourologic surgeon can attempt to treat the stone with caution to expose the proximal ureter and enable safety wire placement. Importantly, without a safety wire in place these maneuvers can worsen obstruction, cause damage to the ureter without an option for immediate stent placement, and necessitate percutaneous nephrostomy tube placement.

If a guidewire cannot eventually traverse the level of obstruction, the procedure should be aborted and nephrostomy tube placement should be considered. If access is achieved but traumatically, a retrograde pyelogram should be performed and ureteral stent placement with deferral of the procedure should be considered if there is extravasation.

### Initial guidewire placement was successful, but a coaxial/dual-lumen catheter or ureteroscope will not advance through the ureteral orifice

First ensure that the bladder is empty; it is not uncommon to neglect to empty the bladder before removing the cystoscope. Careful twisting and advancement of the dual-lumen catheter, which has a tapered tip, can often enable access into the distal ureter. While advancing the catheter over a wire, it is important that the wire remains stationary (secured by the surgeon or an assistant) to allow the catheter to advance without buckling. Inability to advance the catheter may indicate anatomic narrowing or stricture at the ureteral orifice. This necessitates a decision whether a ureteral stent should be placed and the procedure deferred for 5–7 days for passive dilation of the ureter, or whether ureteral dilation should be performed. Fuller et al. determined the failure rate of primary URS in the previously unstented ureter was 7.7% in their multi-institutional study; this rate decreased to approximately 4% when the distal ureter was dilated with balloon or serial dilators [4]. Young female patients and proximal ureteral stones were less likely to be able to be accessed primarily. Viers et al. showed a 16% incidence of access failure that required prestenting at the time of URS. They showed a 4.4% increased risk of requiring prestenting based on a preoperative computed tomography urogram finding of <50% ureteral opacification [5].

Our algorithm usually begins with retrograde pyelography with a dual-lumen catheter. If multiple areas of the ureter appear narrow in addition to the ureteral orifice, we place a ureteral stent and return to the operating room in approximately 1 week. If the ureteral orifice or intramural tunnel appears to be discretely narrow or strictured, several dilation techniques are available.

Ureteral balloon dilation can be performed by advancing a balloon dilator over the wire and ensuring the radiopaque markers span the orifice/intramural tunnel (Figure 45.3). The balloon is filled with contrast and held at 12 cm$H_2O$ for approximately 1 minute. The balloon is then deflated and removed. The dual-lumen catheter can then be advanced over the wire to allow for passage of the second working guidewire (if not already placed). The ideal balloon dilator for this region is 4 cm × 12 Fr, which minimizes trauma to the ureter and the risk of extravasation, and has not been shown to increase the risk of ureteral stricture formation [6, 7]. Active dilation can also be performed with serial dilators (e.g. Nottingham dilators). Finally, dilation can be performed under direct vision with a semirigid ureteroscope.

While dilation may enable access to the ureter, it can be traumatic and cause edema and/or urinary extravasation; thus, it is important to ensure a ureteral stent is placed at the end of the case if dilation is performed. When treating a stone, it is important to be aware that, if a distal stricture is present, residual fragments may not pass after stent removal, and risk of an obstructing fragment or steinstrasse may be increased. A ureteral stricture should be ideally treated prior to the treatment of a more proximal stone, and allowed to heal prior to lithotripsy. Concomitant treatment can increase the risk of submucosal stones or stone granuloma formation, which can lead to stricture disease.

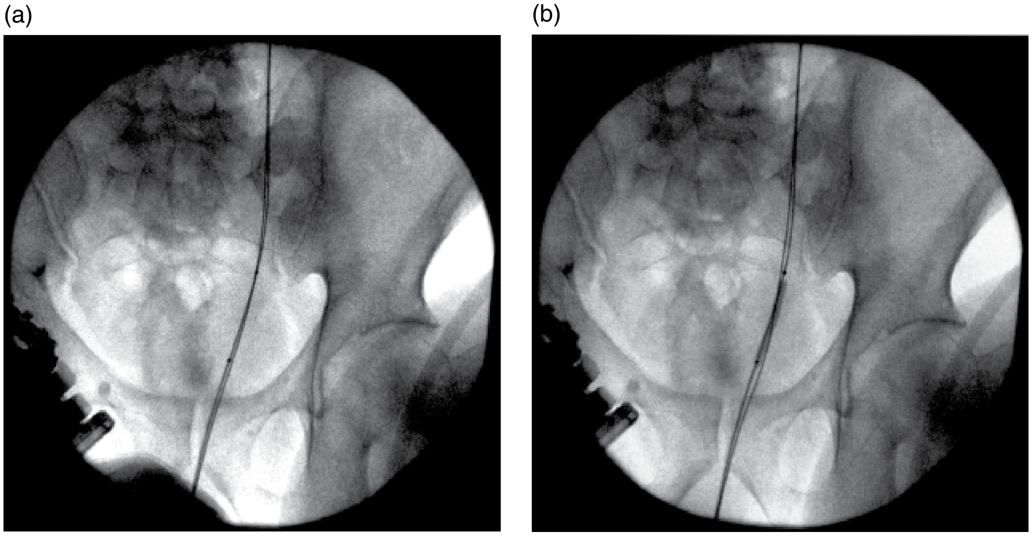

**Figure 45.3** Balloon dilator. (a) 4 cm × 12 Fr ureteral balloon dilator positioned in the intramural tunnel. (b) Balloon expanded to dilate distal ureter/intramural tunnel.

If a dual-lumen catheter will not advance despite balloon dilation, or if balloon dilation is contraindicated (e.g. bleeding diathesis), a ureteral stent should be placed to allow passive dilation of an anatomically tight ureteral orifice or healing of a dilated stricture, and/or to relieve acute obstruction. Without a safety wire it is typically not recommended to proceed with URS when an intervention is anticipated, except in the hands of experienced endourologists. With the newer generation flexible ureteroscopes, URS has been demonstrated to be safe without the use of a guidewire ("wireless") [8].

If a wire has passed but even a stent will not advance through the orifice, a small open-ended catheter can be advanced to the kidney and secured to the Foley catheter; this can allow for retrograde pyelography at the time of nephrostomy tube placement to facilitate placement of the tube, particularly if there is no severe dilation of the collecting system.

With safety and working wires in place, the flexible ureteroscope may not advance through the ureteral orifice or a segment of the ureter. The techniques discussed previously may apply here (e.g. emptying the bladder, holding the wire tautly, balloon or serial dilation). If the ureteroscope will not advance within the ureter, retrograde pyelography should be repeated to ensure there is no ureteral injury. If there is an obstructive lesion, the ureteroscope can be advanced to the level of the lesion and the area examined. With a safety wire in place, the lesion can be treated (e.g. laser lithotripsy of a ureteral stone, endoureterotomy). At any time, if the ureteroscope will not advance despite these efforts, ureteral stent placement can be performed and interval surgery planned.

If at any stage there is evidence of ureteral perforation with extravasation, a ureteral stent should be placed and the ureter should be allowed to heal before re-intervention. There may be new stricture formation from a ureteral injury, and this should be investigated at the time of follow-up surgery. If ureteral avulsion occurs, stent placement should be performed if possible, and the procedure should be aborted. Percutaneous nephrostomy tube placement will likely be necessary, and ureteral reconstruction may be considered in the same sitting if severe injury has occurred to a focal segment (e.g. ureteral reimplantation for an avulsion at the level of the bladder). If more complex reconstruction is required in delayed fashion, percutaneous nephrostomy tube placement should be performed.

During manipulation of multiple wires and catheters, patients can develop bleeding from the upper tract that may obscure visualization. If visualization is significantly compromised, the procedure should be aborted and a ureteral stent placed. Bleeding from the upper tract will typically tamponade, and a stent will allow continued drainage of the kidney. Any uncorrected coagulopathy should be addressed. Severe persistent bleeding with clot retention and/or hemodynamic instability may require continuous bladder irrigation, blood transfusion, and consideration of angioembolization.

Finally, instrumentation of the urinary tract may cause urosepsis in a patient with active infection or colonization. This may occur despite the administration of prophylactic antibiotics, and in particular may occur in patients with infected stones. If a patient develops hemodynamic instability during the procedure and there is consideration for urosepsis, a stent should be rapidly placed along with bladder drainage, and broad-spectrum antibiotics administered until culture results return. If there are signs of purulent urine when accessing the upper urinary tract, cultures should be obtained and the procedure should be aborted until cultures are negative. If this occurs, a ureteral stent (+Foley catheter) should be placed to allow for drainage of the infected urine from obstructed renal moiety.

## Ureteral stenting prior to ureteroscopy

Ureteral stents are most commonly used preoperatively in the setting of infection, presence of a solitary kidney, or compromised renal function, or when other attempts to gain access to the kidney have failed. The most recent American Urological Association and European Urology Association guidelines do not mandate the need for preoperative ureteral stenting in routine patients [9, 10]. However, their use in the pediatric population to passively dilate the ureter has been illustrated [11]. The use of preoperative stenting in the adult population had not been fully elucidated. The Clinical Research Office of the Endourological Society (CROES) recently published their work on the use of preoperative ureteral stenting prior to ureteroscopy. In their population, 11.9% (978 patients) had a ureteral stent placed prior to ureteroscopic intervention. They showed an increased stone-free and decreased complication rate in patients with renal stones. There was no significant difference in measurable outcomes for patients with ureteral stones [12]. In addition to improving clinical outcomes, Averch et al. showed in a retrospective review of 104 patients that the use of preoperative double-J stenting decreased the median cost, reduced operative time, and decreased the reoperative rates for patients with stone burden >1 cm, but no significant difference in patients with stone burden <1 cm [13, 14].

### Ureteral access in patients with urinary diversion

Retrograde ureteral access in patients with prior urinary diversion surgery has been shown to be feasible and safe, although altered anatomy may increase the complexity of these procedures [15–17]. Success of retrograde access may vary depending on the type of diversion and the indication for URS (ureteroanastomotic stricture disease vs surveillance or stone treatment), as well as the experience of the surgeon. In one retrospective study of these patients, 21 renal units underwent attempted retrograde access for diverse indications, and 75% of attempts were successful [15]. The success rate by type of diversion was 90% (9 of 10) for orthotopic neobladders, 73% (11 of 15) for ileal conduits, and 33% (1 of 3) for Indiana pouches. All attempts to access renal units for management of suspected upper tract malignancy were successful (13 of 13 patients, 100%), while attempts were less successful in patients with anastomotic stricture disease (5 of 10, 50%).

Prior to attempted retrograde access in these patients, operative reports should be reviewed to confirm the type of diversion, type of anastomosis (e.g. Bricker vs. Wallace), and likely location of the orifices. A loopogram or cystogram can be performed prior to attempted access to determine patency and location of the orifices, though we do not believe this is routinely necessary. The bladder should be initially accessed with flexible cystoscopy, particularly for pouches or conduits; rigid cystoscopy can be considered in neobladders for direct access to the orifice, particularly in cases of ureteroanastomotic stricture. If a neobladder with a Studer limb has been performed, the afferent limb should be cannulated with a flexible cystoscope and the orifices sought. If the orifices cannot be readily identified, methylene blue or indigo carmine can be administered intravenously to view efflux of dye. Cannulation of the orifice with a flexible guidewire is then attempted (Figure 45.4). If there is difficulty with cannulation because of the location or angle of the orifice, a 5 Fr open-ended or Bernstein angiographic catheter with a straight or angled-tip hydrophilic guidewire can be used. We recommend routine placement of a safety wire in these patients as the initial access may be challenging.

### Ureteral access sheath

UAS are used to facilitate access to the ureter during flexible URS. They are used primarily for flexible URS/holmium laser lithotripsy to enable repeated entry into the ureter with extraction of fragments or to allow for passive egress of fragments. They may also be used for repeated biopsies and treatment of suspicious upper tract lesions (e.g. upper tract TCC). UAS have become standard practice in many institutions for treatment of stone disease in particular; however, routine use of a UAS is still controversial based on concern for ureteral ischemia, ureteral perforation/injury, and questions regarding the ultimate benefit of a UAS for clinical outcomes. Dimensions of UAS include 9.5/11.5, 10/12, 11/13, 12/14, or 13/15 Fr diameter, and 20–55 cm length depending on the manufacturer.

Advantages of using a UAS are both theoretical and practical. They have been shown to decrease intrarenal pressure and may decrease pyelovenous and pyelolymphatic backflow, thus decreasing absorption of irrigant and possibly decreasing the risk of infectious complications, particularly in previously infected patients [18, 19].

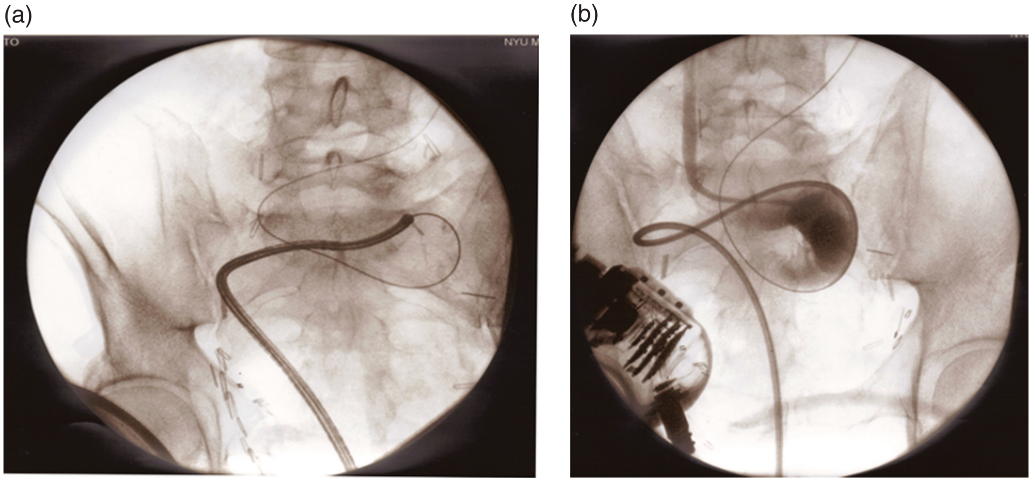

**Figure 45.4** (a) Orthotopic neobladder with Studer limb: access into the left ureter with guidewire. (b) Orthotopic neobladder with Studer limb: cystogram reveals right ureteral reflux. Reproduced from [15] with permission of Elsevier.

UAS improve irrigant flow, which may improve visibility and help to flush out small stone fragments, as well as decrease the need for emptying of the bladder during a protracted procedure. Additionally, Pietrow et al. showed the use of UAS increased the average life span of the ureteroscope prior to being sent out for a repair [20]. There is conflicting evidence regarding the impact of UAS on stone-free rates [21–26] (Table 45.2). There is also evidence that UAS decrease the cost and operative time for treatment of renal stones, but these studies have not been rigorously designed [22].

There have also been objections to routine use of UAS, including risk of acute injury to the ureter and unknown long-term risk of stricture formation [27, 28]. The latter appears low and consistent with standard URS; however, there have been no studies with long-term follow-up [23]. Traxer et al. showed, in 1490 patients undergoing URS with a UAS, an intraoperative complication of 5.9% which included bleeding and perforation as the two most common complications. This was shown to be nonsignificant when compared to patients undergoing URS without UAS (5.6%) [26]. Nonetheless, there is *in vivo* evidence of transient ureteral ischemia with UAS use [29]. Similarly, Razvi et al. showed in farm pigs that prolonged indwelling time and resistance to insertion of a UAS was associated in the short-term formation of ureteral stirctures [30]. Whether this information from a porcine study can be extrapolated to humans is yet to be determined. Furthermore, placement of a UAS may be impeded by a tight ureteral orifice, which may require balloon dilation to accommodate the access sheath; this may increase the risk of extravasation in addition to the time and cost of the procedure. Ultimately, the use of a UAS is at the discretion of the surgeon, and it may be beneficial on either a selective or routine basis.

Placement of a UAS is safest when performed over a working guidewire in the presence of a safety wire. The two components of an access sheath include an inner dilator and an outer sheath. Placement is facilitated by use of a working nitinol guidewire or Amplatz super-stiff wire (not a hydrophilic guidewire), and the access sheath is placed as a unit to the desired level within the ureter, at which point the inner component is withdrawn (Figure 45.5). It is important that all components of the access sheath are wet as the surfaces are hydrophilic. The access sheath may be secured to the drape to ensure it does not dislodge. The level of placement depends on the clinical scenario; for a renal stone, placement in the proximal ureter is typical to protect as much ureter as possible during entry and re-entry. Newer versions of access sheaths have also been created that allow passage of the sheath over only one wire, and when the inner dilator is removed, the guidewire is left on the outside of the sheath to serve as a safety guidewire.

Placement of a UAS can be compromised by an anatomically tight ureter or ureteral stricture disease. If the UAS cannot be placed through the orifice, balloon dilation may be performed. While some surgeons dilate the orifice on a regular basis for UAS placement, others will simply abort use of the sheath and continue without it. It has not been rigorously studied whether one approach is superior to the other from the standpoints of safety or stone clearance. Kuntz et al. looked at the risks of ureteral balloon dilation and found in 151 patients a failure of balloon dilation in 5% and an intraoperative ureteral perforation in 5%. Patient who experienced ureteral perforation were managed with either immediate ureteral stenting or percutaneous nephrostomy tube. The determined postoperative complication arte was 8% and a single ureteral stricture (0.6%) was attributed to balloon dilation [31].

**Table 45.2** Series of UAS use for treatment of upper tract calculi.

| Study | Number of patients | Size of sheath | Number of balloon dilations (%) | Mean size of stone (mm) | Successful placement (%) | Stone-free rate | Complications |
|---|---|---|---|---|---|---|---|
| Traxer et al. 2015 [26][a] | 1494 | Not mentioned | Not mentioned | 10.8 | 99.2 | 73.9 | Perforation (17), converted (3), sepsis (7), acute abdomen (2) |

[a] Propsective, observational, international, multicenter study of UAS (1494) versus no UAS (745); there was a statistically higher stone-free rate in non-UAS (73.9% vs. 82.8%, $P < 0.01$).

[b] Prospective randomized study of UAS (23) versus no UAS (21); there was no difference in stone-free rate (78.9% vs. 85.7%; $P = 0.78$).

[c] Retrospective comparative cohort study of UAS (173) versus no UAS (83); stone-free rate was improved overall by use of a UAS (79% vs. 67%; $P = 0.04$).

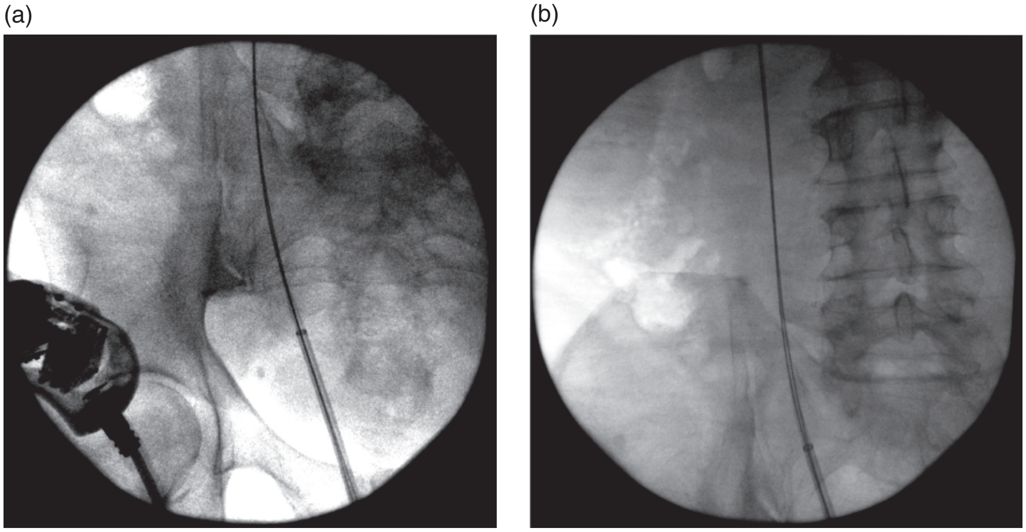

**Figure 45.5** UAS placed in (a) distal ureter and (b) mid ureter.

Finally, when placing an UAS, it important to be aware of small ureteral stone fragments that can be trapped alongside the sheath and are at risk for being pushed submucosally. If unrecognized this can lead to an impacted stone, or possibly a submucosal stone that can cause ureteral obstruction secondary to stricture formation.

We recommend placing a ureteral stent at the end of any procedure in which a UAS is used, although there is some evidence that this may not be necessary in previously stented patients [32]. Rapoport et al. retrospectively reviewed a series of consecutive patients who underwent URS for renal and ureteral stones, and found that use of a UAS without postoperative stenting significantly increased the risk of unplanned emergency room visits with increased emergency computed tomography scans, hospital readmission, and need for urgent decompression [33].

## Conclusions

Access to the ureter for flexible URS is typically straightforward, but can be complicated by both anatomic and disease factors. Anticipation of the "next step" and planning for difficult access can maximize the likelihood of success in these cases. Repeated entry to the ureter for flexible URS can be facilitated by use of a UAS, although the precise risk-to-benefit ratio of UAS is not known.

# Ureteroscopy Energy Sources

*Daniel A. Wollin & Glenn M. Preminger*

*Division of Urology, Department of Surgery, Duke University Medical Center, Durham, NC, USA*

## Introduction

With endoscopic technology allowing excellent access to urinary stones, ureteroscopic treatment of nephrolithiasis has become a primary option in many cases. According to the 2016 American Urological Association and Endourological Society Guidelines for Surgical Management of Stones, ureteroscopic treatment is first-line for all ureteral calculi, as well as for intrarenal stones less than 20 mm [1, 2].

While smaller stones can be extracted intact, urinary calculi frequently require fragmentation prior to removal. As flexible and semirigid ureteroscopic technology provides better access to stones, adjunctive tools, including stone manipulation devices and lithotripters, have similarly become more advanced. In addition to efficiency and safety of intracorporeal lithotrites, newer fragmentation devices require reduced size and increased flexibility to allow for use with third-generation ureteroscopes.

Given the wide array of intracorporeal lithotrites, the endourologist must be familiar with each device, including mechanism of action, to appropriately choose the treatment for stones of various sizes, compositions, and locations (Figure 46.1). In this chapter, techniques for ureteroscopic lithotripsy will be discussed, with focus on the differences between each method, including their advantages and disadvantages in various clinical situations.

## Electrohydraulic lithotripsy

### Overview

Electrohydraulic lithotripsy (EHL) was the first method for intracorporeal lithotripsy utilized in clinical applications. The technology, first invented by Yutkin in 1955 at the University of Kiev, was used for upper tract stones during an open nephrolithotomy in 1975 [3, 4]. Since that time, EHL probes have been miniaturized for use in rigid and flexible ureteroscopes for treatment of ureteral stones [5, 6]. Despite its effectiveness and low cost, it is rarely used because of the high risk of ureteral injury. Yet, its low cost still makes EHL an option in certain situations.

### Technology

The mechanism for EHL fragmentation involves discharge of electrical energy in a liquid medium. The probe is composed of two electrodes of different polarities; a current passes between the electrodes and the energy release forms a plasma channel and vaporization of nearby water. This vaporization creates a shock wave and cavitation bubble, whose collapse creates secondary shock waves or high-speed microjets, all of which cause stone fragmentation.

### Advantages/disadvantages

The advantage of EHL is the low cost of components. The EHL generator and probes are currently less expensive than other intracorporeal lithotripters, with one or two probes used per procedure depending on stone composition [7, 8]. Additionally, modern EHL probes are small and flexible, allowing for treatment of stones through all types of ureteroscopes.

The main disadvantage of EHL is high risk of intraoperative injury. Initial experience of EHL reported high complication rates, as the lithotripsy was performed with large probes (9 Fr) and without endoscopic guidance [4, 9]. With improvement in endoscopic visualization, decrease in probe size (to 1.6 Fr), and improved control of energy output, EHL has become safer, although the

complication rate remains high, between 6 and 17.6% [6, 10–12]. Complications of EHL range from ureteral perforation and hemorrhage to mucosal erosion, inflammation, and ureteral stricture.

Studies have been performed to understand the mechanisms by which EHL causes ureteral injury. In addition to direct injury to the ureteral wall from firing of the probe onto mucosa, expansion of the cavitation bubble may induce a burst effect on the ureter [11]. With energy of more than 1300 mJ, the cavitation bubble can reach 1.5 cm in size; thus, decreasing the energy can reduce capacity for injury. One *in vitro* study demonstrated that 24 pulses to the ureteral wall were sufficient for perforation from 0.5 mm, highlighting the care needed while using EHL [13].

The stone fragmentation and clearance rates are not significantly higher for EHL than for newer lithotripters. In addition to fragment retropulsion, which appears more common than with other methods, EHL produces more and larger fragments, reducing stone clearance [14]. EHL is less effective with harder and larger stones (>1.5 cm) and the stone-free rates range widely from 67 to 98% [7].

### Technical tips

Given its risks, EHL should be performed under careful attention and with the lowest power settings that can produce fragmentation. Smaller probes (1.6–1.9 Fr) should be used to decrease perforation risk and to improve irrigation. Prior to use of the lithotripter, insulation layers of the probe should be examined to ensure they are intact. The distal tip of the probe should be placed 2–5 mm from the end of the ureteroscope to reduce damage to the lens, while the probe should be kept 1 mm from the stone to improve shock-wave interaction [15].

Visualization of the stone must be maintained, along with adequate irrigation to distend the ureter away from the probe, to reduce risk of injury. Lithotripsy should begin with low voltage (50–60 V) and single pulses with a slow increase in generator output until the fragments are small enough for basket removal. After 60 seconds of firing, the probe should be examined for loss of insulation, as a new probe may be required. Care must be taken to avoid firing upon any safety wire or retrieval device, as these are damaged by EHL energy.

## Ballistic/pneumatic lithotripsy

### Overview

Similar to EHL, ballistic and pneumatic lithotripsy is an older method of fragmentation. These lithotripters come in many sizes and types of energy production and all necessitate a straight probe during use. The rigid probes decrease the practicality of this technology for upper tract stones requiring flexible ureteroscopy. Still, ballistic and pneumatic lithotripsy remains safe and effective when used in the proper setting.

### Technology

Ballistic and pneumatic lithotrites pass energy from a projectile to the probe (0.8–3.0 mm) and then directly to the stone with a "jackhammer" effect. When fired repeatedly (on the order of 12 Hz with automatic lithotripters), this production of 2–30 atm at the stone surface causes cracking and fragmentation.

Production of this ballistic energy varies between lithotripters, with use of large-scale compressed air (Lithoclast, Electromedical Systems/Boston Scientific), handheld high-pressure $CO_2$ cartridges (StoneBreaker, LMA Urology/Cook Medical), or electromagnetic acceleration of a magnetic core (LithoBreaker electrokinetic probe, Electromedical Systems). In each case, the probe is held in contact with the stone to transmit the ballistic energy. This method requires energy transfer through a rigid probe; bowing of the device reduces power transmission, limiting the utility of this method to unflexed endoscopes.

### Advantages/disadvantages

Ballistic lithotripsy is a low-cost option. Disposable costs are minimal, as probes have a long life span, unlike laser and EHL [10]. While free-standing pneumatic lithotripters require more expensive consoles compared to EHL, there is minimal maintenance and no disposable costs. The handheld pneumatic lithotripter is less expensive and the disposable $CO_2$ cartridges, which deliver approximately 80 shocks each, add minimal cost to the device.

Ballistic and pneumatic lithotripsy, utilizing direct mechanical energy transfer, are safe compared to other technologies. In contrast to EHL, ultrasonic lithotripsy, and holmium laser, ballistic lithotripsy causes less injury and has lower risk of ureteral perforation [16]. After 6 minutes of direct application of pneumatic lithotripsy to a ureteral wall *in vitro*, no perforation was seen [13]. Additionally, thermal injury is unlikely as minimal heat is produced. Compared to the relatively slow comminution of laser fragmentation (which is discussed later), ballistic lithotripsy has a more rapid stone clearance time [17, 18].

Despite its safety and low cost, ballistic lithotripsy has slightly lower success than other methods, likely secondary to its inability to fragment stones when torqued and the high risk of stone retropulsion. Stone-free rates after ballistic or pneumatic lithotripsy range from 70 to >90%, although the lower rates occur in settings of probe deflection and retropulsion [19–21]. Through a flexible ureteroscope, deflection of more than 24° will significantly reduce energy transmission; distal semirigid ureteroscopy allows for decreased need for flexion and decreased power loss [22]. Thus ballistic lithotripsy is very effective through a semirigid ureteroscope for mid/distal ureteral stones.

The other disadvantage of ballistic lithotripsy is its retropulsion rate, which has been reported in 2–17% of ureteroscopic treatments. Due to this high rate of retropulsion, especially given the rigid lithotripter, migration into the proximal ureter or kidney can render stone fragments untreatable with this method alone. Many tools have been developed to prevent stone migration, including stone-trapping devices (such as stone baskets, gel polymeric plugs, and ureteral balloons) and suction devices to be used alongside the lithotripter [23, 24]. These methods reduce the risk of retropulsion and improve fragmentation efficiency and stone-free rates, although careful use of the lithotripter may preclude the need for such techniques [25, 26].

### Technical tips

As with all lithotripters, endoscopic visualization of the stone is a prerequisite for treatment. The stone should be pinned in place for fragmentation and to decrease retropulsion, whether held against urothelium or using a trapping mechanism. Bending of the endoscope or probe should be avoided in order to maintain power during lithotripsy. The probe must be in contact with the stone and it is recommended to work from the periphery to separate fragments small enough for spontaneous passage. Given the minimal flexibility of this device, if larger fragments migrate proximally, chasing and treating such pieces becomes problematic.

## Ultrasonic lithotripsy

### Overview

Ultrasonic lithotripsy was described by Mulvaney in 1953, with the first ureteral applications in the 1970s and 1980s [27, 28]. This method uses ultrasonic vibrations to fragment calculi; many ultrasonic lithotripter probes include a suction channel to allow simultaneous fragment removal. Similar to ballistic lithotripsy, this requires a rigid device, reducing the utility of ultrasonic lithotripsy during ureteroscopy. Smaller probes (2.5 and 4.5 Fr), with or without suction capabilities, can be used through a semirigid ureteroscope with success and safety.

### Technology

The ultrasonic method of lithotripsy utilizes an electrically charged piezoceramic plate within the transducer that resonates at high frequency (23 000–25 000 Hz) and generates ultrasonic waves. These longitudinal and transverse waves are passed along a hollow steel probe, which makes contact with and fragments the stone. Fragmentation occurs as noncompliant stone material is vibrated at a high frequency such that the stone breaks; compliant tissue (e.g. urothelium) does not resonate in this manner and inadvertent damage is minimal [3, 29].

Due to vibration of the ultrasonic probe, heat development is a concern, but most probes allow for concurrent suction through their core, which enables irrigation flow and heat dispersion. With adequate irrigation/suction and intermittent probe firing, temperature increase can be minimized [30]. The probes are reusable but will incur damage: periodic replacement is required.

Of note, combination lithotripters exist that allow for ultrasonic and ballistic fragmentation (Lithoclast Ultra/Select, Electromedical Systems/Boston Scientific) or dual-probe ultrasonic lithotripsy (CyberWand, Gyrus ACMI/Olympus). These technologies allow for improved fragmentation and suction, but are only available in the percutaneous setting given their size and rigidity [31, 32].

### Advantages/disadvantages

The advantages of ultrasonic lithotripsy are rapid fragmentation along with concomitant fragment removal. Studies report stone-free rates from 88 to 98%, making this an effective method [33–35]. These success rates are seen throughout the literature using ureteroscopic probes of 4.5 Fr (hollow probe with suction) or 2.5 Fr (solid probe without suction). Still, the capability for simultaneous removal of small fragments during lithotripsy is beneficial. This suction ability is particularly useful in a setting of steinstrasse, as the stone debris can be continuously evacuated.

An advantage discussed previously is the relative safety of the ultrasonic mechanism. Due to the method of vibrational energy transmission, flexible material – such as ureteral tissue – is not damaged easily. *In vitro*, the ultrasonic device has the longest average time to urothelial perforation, with injury occurring at 118 seconds of continuous firing in direct wall contact [29]. Probe temperature rise is a concern, but is managed with adequate irrigation.

Despite these advantages, this method is only utilized in semirigid ureteroscopy. If suction is necessary, a ureteroscope with a large working channel is required for passage of the 4.5 Fr probe. While the 2.5 Fr solid probe is smaller, semirigid ureteroscopy is still required for use of this device. Given its inability to be used with a flexible ureteroscope, this technology is typically restricted to percutaneous surgery, where rigid nephroscopes allow passage of larger and more powerful ultrasonic probes.

### Technical tips

Endoscopes with minimal flexion and large working channel are required for rigid probe use. Gentle pressure against the stone is required, although suction capabilities or simultaneous use of a stone-trapping device can reduce the need for pressure and decrease the risk of urothelial injury. With larger ureteroscopic probes, suction allows for concurrent removal of small stone fragments during lithotripsy. Fragmentation is most efficient when performed along the stone periphery to produce smaller pieces that are suctioned away. To reduce heat production, continuous high-flow irrigation is recommended along with intermittent probe firing.

## Nanosecond electropulse lithotripsy

### Overview

Nanosecond electropulse lithotripsy (NEPL) is the newest method of intracorporeal lithotripsy, described in 2007 [36]. It utilizes similar technology to EHL, although due to different characteristics of energy discharge it has a better safety profile. Early data show similar ease of access and flexibility compared to laser/EHL, along with excellent fragmentation, making this a promising new method for lithotripsy.

### Technology

While EHL and NEPL probes contain two distal electrodes across which current is applied, the NEPL probe differs due to the voltage and time over which energy is released. In contrast to EHL discharge time of hundreds of microseconds at low voltages, NEPL releases higher voltages in less than 50 nanoseconds. This method of energy release, when the probe is touching a non-conducting material such as urinary calculi, produces spontaneous conduction and direct electrical breakdown of the target. In the absence of a solid target, the probe performs similarly to EHL and releases energy into the surrounding fluid, creating a shock wave and cavitation bubble. The focus of electrical energy into the target (instead of the surrounding fluid) is what provides the proposed safety of NEPL.

### Advantages/disadvantages

NEPL has become the focus of recent studies given the potential for improvement over previous technology.

*In vitro* studies have shown improved energy and time efficiency compared to EHL and laser lithotripsy [37–39]. Stone-free rates are comparable to other methods, with 91–100% success depending on the stone location (mid ureter with better success than upper ureter) [36]. This high success rate is likely related to the efficiency of the treatment as well as the ease of access allowed with the small, flexible probes (2.7 or 3.6 Fr) along the upper urinary tract.

The safety profile of NEPL is generally favorable, although more data are needed. *In vitro* studies have documented nonperforating injury isolated to the submucosal or muscular layers after 10 pulses of 1.0 J [40]. Additionally, in a study of 799 patients with ureteral stones undergoing NEPL, 18 ureteral perforations occurred (2.1%), although most perforations were related to torque of the semirigid ureteroscope, not energy dispersal [36].

The disadvantages of this technology are the potential for retropulsion and lack of information about this new lithotripsy method. Rates of retropulsion are approximately 5%, although this is less of a concern than with rigid lithotripters, as access to the kidney is more feasible with the flexible NEPL probes [36]. While the mechanism of action and safety have been studied, this technology is still in its infancy. Additional studies are needed to document its utility and safety before widespread use. Still, the advantages give this technology a chance to become a strong addition to the endourologists' arsenal.

### Technical tips

As NEPL use is not widespread and there are few recommendations on use, although it is expected that treating this method similarly to EHL would produce safe and effective results. As such, ureteroscopic visualization of the stone is of paramount importance to ensure probe contact throughout treatment. By maintaining contact with the stone, risk of shock-wave formation is theoretically decreased, preventing complications seen with EHL. Higher power is required for electrical breakdown of the stone; therefore, care must be taken with probe placement prior to firing. Additional studies will better evaluate the risk for retropulsion, but preliminary data suggest that standard methods to reduce retropulsion may be beneficial.

## Laser lithotripsy

### Overview

Laser lithotripsy is the most commonly used method of intracorporeal stone fragmentation. Laser, which is an acronym for **l**ight **a**mplification by **s**timulated **e**mission of **r**adiation, involves transmission of energy to the target in a directed, collimated beam of photons of a single wavelength. Depending on the wavelength, power, pulse length/frequency, and method for beam delivery, the mechanism and efficacy of stone fragmentation differs wildly. Still, urologic lasers have excellent safety and probe flexibility and, despite slower fragmentation, they are widely utilized for ureteroscopic lithotripsy.

Clinical laser technology was developed in 1960 by Theodore H. Maiman, while 6 years later Parsons was first to experiment with this device in urology, testing a pulsed-ruby laser in canine bladders [41, 42]. In 1968, Mulvaney and Beck reported this ruby laser could fragment urinary calculi, although it was clinically unsafe given excessive heat generation [43]. Since that time, there has been improvement within the field of laser physics to allow for safer and more efficient tools for treatment of urinary stones.

### Technology

Laser energy is produced when a material – gas, liquid, or solid – known as gain medium, is stimulated by an energy source; photons are released as excited electrons return to their normal state. Photons released in this manner contain a large amount of energy as the beam is in-phase, collimated, and of a single wavelength. Amplification occurs as mirrors refocus the beam, producing further excitation and emission. The beam is then released as a continuous wave, or a mechanism induces an intermittent or pulsed quality, which has profound effects on the physics of energy transfer. The laser is then carried along a fiber where it is released upon the target.

Many types of gain medium have been used, from $CO_2$ gas (which produces a continuous beam of 10 600 nm wavelength light) to organic liquid dye (e.g. coumarin, which generates a tunable short-pulse laser) and solid crystals (e.g. ionically doped yttrium aluminum garnet; YAG). Each laser is named for the medium used; the choice will affect the characteristics of the laser generated. Additionally, these characteristics will produce different responses in the target, as these variations lead to differing methods of energy transfer.

Laser energy transfer in lithotripsy is described in two forms: photomechanical and photothermal. Photomechanical ablation occurs when a short-pulse laser produces transient stress waves in the surrounding medium, leading to formation of shock waves from plasma or cavitation bubble formation and collapse [44]. Since the shock wave from bubble collapse propagates in all directions, the fiber can be placed anywhere near the stone, although distance is required for bubble expansion [45]. Photothermal ablation, on the other hand, involves direct absorption of longer-pulse laser energy into the stone crystal lattice or water molecules within the crystal. In this method, direct transfer of energy to the stone produces fragmentation and contact is needed between the fiber and target for lithotripsy to occur. In photothermal ablation, laser energy is highly absorbed by water and, when fiber and stone are not in contact, energy is lost in vaporization of a water channel before it reaches the stone ("Moses effect") [46]. Compared to creation of shock waves in photomechanical fragmentation, which leads to large stone fragments, the direct energy transfer of photothermal fragmentation typically produces smaller dust-like debris [47].

The laser fiber allows for direction and delivery of the photon beam to the target and an ideal fiber should be small, flexible, durable, and able to transmit energy with efficiency. The basic fiber design consists of core material (typically silica) surrounded by two or three layers of cladding and protective coating. Since laser output is not ideal and perfectly collimated, there is frequent delivery of off-axis rays that undergo internal reflection during passage of the beam along the fiber; with large amounts of fiber flexion and beam divergence, energy can be transmitted through the cladding and cause fiber, ureteroscope, and patient injury [48]. The fiber tip also has a strong effect on the output, although this has mostly been studied in the holmium:YAG (Ho:YAG) setting. Tip degradation is typical over the course of a procedure, and multiple stripping/cleaving techniques are thought to prolong the use of the fiber [49, 50]. Despite this manipulation being common practice, latest data call into question the efficacy of these maneuvers, showing that stripped fibers have a lower power output and increased tip degradation [49, 51].

Recently, ball-tip fibers have been developed to allow smoother passage through deflected ureteroscopes with hopes of minimizing damage to the working channel. While these delicate tips degrade rapidly at higher energy settings, comminution efficiency of the ball-tip fiber is comparable to standard fibers. Moreover, in low-energy, high-frequency laser settings the ball tip remains intact. Most importantly, the ball tip appears to be protective of the working channel as a decreased force is required for insertion in deflected ureteroscopes [52, 53].

## Laser types

The pulsed-dye laser was one of the first used for clinical treatment of urinary stones. It used a coumarin green dye as laser medium and produced a short-pulse beam with 504 nm wavelength. This wavelength of light is well absorbed by hemoglobin, utilizing the bloodstream as a heat sink and making the laser safe *in vivo* [45]. Pulsed-dye lasers utilize the photomechanical effect and, therefore, are not effective at fragmenting harder stones such as calcium oxalate monohydrate, brushite, and cystine [54]. Given this disadvantage, along with the toxicity of the dye, this laser has fallen out of favor and is rarely used.

Neodymium-doped YAG crystal is used as the medium for the frequency-doubled double pulse Nd:YAG (FREDDY) laser, within which a potassium titanyl phosphate (KTP) crystal is placed to create pulses of two different wavelengths (532 and 1064 nm). This dual-wavelength laser creates a plasma bubble on the surface of the stone, and collapse of this bubble induces fragmentation through photomechanical effects. Similarly to the pulsed-dye laser, this energy must be delivered within a 3 mm distance, is absorbed by the bloodstream and has a very low risk of ureteral perforation [13, 55]. This laser has excellent efficiency – even compared to Ho:YAG – but with a significantly increased risk of retropulsion, inability to fragment harder stones, and similar costs, it is no longer commonly utilized clinically [56].

The Ho:YAG laser is currently the workhorse of ureteroscopic lithotripsy [57]. This laser uses a holmium-doped YAG crystal to create a 2140 nm wavelength pulsed beam. The pulses of this laser are longer (250–350 microseconds) than the dye lasers, leading to a largely photothermal effect on the target. Many studies have been done to evaluate the energy transfer in holmium laser lithotripsy and have noted minimal photomechanical effects. A weak shock wave is noted during holmium lithotripsy and fragmentation begins before cavitation bubble collapse and shock-wave formation [58]. Additionally, holmium laser lithotripsy is improved with warmed stones, with dry stones fragmented in air rather than irrigation, and when the laser is discharged with minimal incident angle, all pointing towards a direct transfer of energy and photothermal mechanism of action [59].

The Ho:YAG laser has many advantages that allow widespread use. There are multiple fiber sizes (200, 365, 550, and 1000 μm) utilized for ureteroscopic lithotripsy, but the 200 μm fiber allows for excellent flexibility and irrigation flow compared to other lithotripters, improving ureteroscopic access to the entire collecting system [60]. The 365 μm fiber is used primarily during semirigid ureteroscopy. In contrast to older lasers, the photothermal mechanism of action allows for fragmentation of all stone compositions, including cystine and calcium oxalate monohydrate. Additionally, with maximum penetration of approximately 1 mm and minimal shock-wave formation, the holmium laser is very safe for use in the urinary tract, even in patients with bleeding diatheses [13, 57, 61]. The modest shock wave also reduces risk of retropulsion, although increasing pulse energy can induce a more significant shock wave and increase retropulsion risk [56, 62]. In combination with – and because of – these advantages, holmium laser lithotripsy enjoys an excellent success rate, with current stone clearance rates typically between 86 and 98% [19, 20, 63].

Despite these advantages, Ho:YAG laser does have shortcomings. The drilling mechanism of lithotripsy that this laser utilizes produces relatively small fragments, which leads to longer procedures and less efficient lithotripsy [64]. Still, while occasionally inefficient, this allows for the "dusting" method of lithotripsy discussed in a following section. Despite its excellent safety profile, holmium laser does have the capability to injure the urothelium and endoscopes – as well as adjunctive devices such as basket and antiretropulsion devices – if not carefully directed, with an approximate risk of 1%. Retropulsion is not a large concern with this laser, although it can still occur during ureteroscopy and pulse energy must be managed accordingly. Lastly, holmium laser requires a relatively expensive laser generator and the majority of fibers are nonreusable, requiring comparatively high costs (Table 46.1).

## Technical tips

Given that Ho:YAG laser is most frequently used, recommendations within this section will focus on its use. Similar to other methods of ureteroscopic lithotripsy, adequate visualization of the stone is required. The laser fiber should be placed against the stone with care taken to avoid firing upon the urothelium or other endourologic equipment as they can be damaged by the laser. Additionally, the fiber should be extended at least 2 mm from the tip of the ureteroscope to prevent damage to the fiberoptics or digital chip.

A variety of power settings are utilized for ureteroscopic lithotripsy with the Ho:YAG laser, depending on the method of fragmentation planned. A high-energy, low-frequency setting (e.g. 1.2 J and 5 Hz) will produce deeper and wider fissures than a low-energy, high-frequency setting at the same power, suggesting that this type of fragmentation is most energy-efficient [65]. This method produces larger fragments, increased risk of retropulsion, and leads to quicker degrading of the fiber, thus it is not always the most useful setting [52]. A low-energy, high-frequency method of laser discharge (e.g. 0.2 J and 50 Hz) reduces the risk of retropulsion and allows for the "dusting" technique for stone fragmentation. In this technique, the laser fiber is "danced" across the surface of softer stones, producing submillimeter particles that are easily passed; this method reduces the number of fragments that require removal at the conclusion of the fragmentation. There are not sufficient data to evaluate whether dusting or fragment removal is more efficient, although studies are underway.

**Table 46.1** Comparative costs of ureteroscopic lithotripter devices.

| | EHL | Pneumatic | Ultrasonic | NEPL | Laser |
|---|---|---|---|---|---|
| Probe | $ | $$ | $$ | $ | $$$$$ |
| Generator | $ | $$ | $$ | $ | $$$$$ |

"Popcorning" is another technique where stone fragments are isolated within a calyx and high-energy, high-frequency settings (such as 1.0 J and 20 Hz) are used to agitate the stones; this method intermittently brings the fragments into contact with the fiber and further fractures the pieces [66]. Given all possible settings and minimal research comparing the options, it is recommended to start with relatively low energy settings and increase the energy and/or frequency depending on the planned method of fragmentation and clinical situation.

The overall power output of the laser generator is also of clinical significance, as it determines the maximum values of laser energy and frequency possible. The typical Ho:YAG generator produces 80 W of power and this generator has been the most commonly studied and used for intracorporeal lithotripsy. Given the cost of this generator, low-power and cheaper Ho:YAG generators have been evaluated for similar outcomes. While they do not allow for higher power settings (such as 1.5 J and 30 Hz), low-power lasers (10–30 W) are useful in all urologic procedures – except for prostatic ablation or enucleation – and are capable of intracorporeal lithotripsy [63, 67]. Conversely, new high-power lasers (120 W) are being utilized in certain situations, primarily for managing benign prostatic hyperplasia, although data are currently lacking regarding the improvement over standard power generators for stone fragmentation.

A final technical recommendation regarding use of Ho:YAG laser involves changes in pulse duration, which was recently evaluated with regards to fragmentation efficiency and risk of retropulsion. At a set power level, shorter pulse duration allows for a more concentrated discharge of energy, which produces more significant retropulsion and fiber damage compared to a longer pulse [68, 69]. Conversely, a shorter pulse may lead to increased fragmentation efficiency, thus the advantages and disadvantages of different pulse lengths must be taken into account [70]. Newer laser generators allow for alteration of pulse duration, as well as energy and frequency, giving the surgeon an additional layer of refinement regarding laser use.

While Ho:YAG laser is the most commonly used method for intracorporeal lithotripsy, advances are being made to bring newer and more efficacious laser technologies to clinical use. The erbium:YAG (Er:YAG) laser, which is used in dentistry and ophthalmology, has a significant increase in lithotripsy efficiency compared to Ho:YAG

**Table 46.2** Overall advantages and disadvantages of ureteroscopic lithotrites.

| | Advantages | Disadvantages |
|---|---|---|
| EHL | Inexpensive, versatile, deflectable | Low safety, poor visibility |
| Pneumatic/ballistic | Efficient, inexpensive/reusable probe, safe | Rigid probe, retropulsion |
| Ultrasonic | Reusable probe with suction capability, efficient, safe | Large, rigid probe |
| NEPL | Efficient, deflectable | Minimal clinical data |
| Laser | Multipurpose, fragments all stones, deflectable, safe | Inefficient, expensive |

*in vitro*. Lee et al. tested stones of multiple compositions and, likely due to high absorption of energy at its wavelength of 2.9 μm, the Er:YAG laser outperformed the Ho:YAG by two to three times [64]. This laser requires stronger and larger fibers for transmission of the beam, and while sapphire or fluoride fibers may become a feasible option, at this time this laser is excluded from clinical use in urology [71]. Similarly, the tunable thulium laser is a newer technology that, with a wavelength of 1908 nm, may have improved efficiency over Ho:YAG laser. This low-energy, high-frequency laser, which fires at speeds up to 1000 Hz, produces comparable ablation along with lower risk of retropulsion and ureteral injury [72, 73].

## Conclusions

There is a variety of ureteroscopic lithotripter options available to the urologist. Given the range of techniques, an understanding of each lithotripter is required to choose the proper tool for each clinical situation and to safely use each technology (Table 46.2). The endourologist must factor in stone type, stone location, patient anatomy, and desired method of fragmentation before finalizing the treatment plan. As endoscopic technology improves, fragmentation devices will advance, but the basic tenets of safe and effective ureteroscopic lithotripsy will remain constant.

## Introduction

Improvements in technology over the last 15–20 years have led to an increased ability to successfully manage ureteral calculi using a variety of methods. Although extracorporeal shock-wave lithotripsy, antegrade percutaneous approaches, and laparoscopic ureterolithotomy are options, the mainstay in the treatment of patients with ureteral calculi continues to be retrograde ureteroscopic stone removal [1]. Refinements in ureteroscopic technology, as well as the development of improved laser techniques and advances in ancillary equipment, such as baskets, graspers, and others, have led to a situation in which almost all ureteral calculi can be successfully managed in a single procedure using ureteroscopy (URS).

Despite these advances, the selection of the single best approach to treat patients with ureteral stones remains controversial, especially given the complexity of today's changing healthcare environment. As there is increasing public focus on less invasive treatment strategies, it should be kept in mind that such approaches may in some cases lead to higher treatment failure rates with the need for secondary procedures. Additionally, a variety of economic factors have increased in importance in all areas of healthcare, and ultimately the most cost-effective approach to ureteral stones may be deemed best for all patients.

In this chapter, we will review the use of URS in relation to other treatment options for patients with ureteral calculi and discuss the wide variety of equipment and instruments that can be used with this procedure.

## Treatment options

There are several management options for patients presenting with ureteral calculi and a multitude of factors that guide clinical decision-making in this setting. Carefully selected patients can be managed conservatively with observation during a trial of spontaneous passage. These are patients with mild-to-moderate symptoms that can be controlled with oral analgesics, and those who do not have any factors that would warrant immediate intervention. These factors include urine infection – especially in an immunocompromised patient – compromised renal function, obstructed solitary kidney, intractable nausea and vomiting preventing adequate hydration, and inadequate pain control. The likelihood of stone passage also has an important impact on the decision to proceed with intervention versus observation. Stone size (measured in the transverse dimension) is an important factor to consider. Based on meta-analysis performed by the 2007 European Association of Urology (EAU)/American Urological Association (AUA) Nephrolithiasis panel, stones measuring 5 mm had a spontaneous passage rate of 68% (95% confidence interval [CI] 46–85%) and stones measuring between 5 and 10 mm yielded a spontaneous passage rate of 47% (95% CI 36–59%) [2]. The use of medications to promote spontaneous stone passage – so-called medical expulsive therapy (MET) – has come into favor over the last several decades. The goal of MET is to reduce time to stone passage, decrease pain/colic episodes, decrease pain medication requirements, and decrease need for procedural intervention. The pathophysiology of ureteral obstruction involves increased ureteral pressures and decreased frequency of ureteral contraction. Given this, it has been hypothesized that relaxation of the ureter and decreasing pressure should promote stone passage. Several classes of medications have been studied, including alpha-blockers, calcium channel blockers, nonsteroidal anti-inflammatory drugs (NSAIDs), steroids, and others; however, the evidence for the use of MET remains controversial [3].

Seitz et al. conducted a meta-analysis of published literature concerning the use of MET in patients with ureteral stones [4]. For 47 randomized controlled trials they assessed the use of alpha-blockers and calcium channel blockers in patients with untreated ureteral calculi of varying sizes. Their results demonstrated that the use of either medication led to a higher and faster stone expulsion rate compared to the control groups. In addition, treated patients had lower analgesia requirements, fewer episodes of colic, and fewer hospitalizations. In contrast, other recent work has called these and other similar findings into question. A study of emergency room patients with small ureteral stones (mean 3.6 mm) examined the rates of spontaneous stone passage at 14 days. Patients were randomized to ibuprofen, oxycodone, and tamsulosin, or ibuprofen and oxycodone alone. There was no difference in their primary outcomes nor pain scores, unscheduled emergency room or primary care visits, days out of work, analgesic use, or adverse events [5].

The largest multicenter, randomized, placebo-controlled trial (SUSPEND trial) included 1167 patients randomized to tamsulosin, nifedipine, or placebo and examined outcomes including rate of spontaneous passage by 4 weeks and cost measures [6]. The results of this study showed no difference in rates of spontaneous stone passage between treatment arms and placebo and between the two treatment arms. In addition, there was no increase in cost-effectiveness of MET versus placebo. Despite the controversial evidence, the practice of MET remains accepted and is still endorsed by the most recent AUA Nephrolithiasis Clinical Guideline Panel [7].

The decision to proceed with a trial of spontaneous stone passage as the initial management approach is often largely based on patient preference. With the exception of the indications for immediate intervention listed above, most patients can at least be offered the opportunity to pass the stone spontaneously. In our experience, some patients with ureteral calculi who have well-controlled symptoms react negatively if a urologist is perceived to be "too aggressive" in recommending an immediate procedure, and may lose confidence in this urologist and end up seeking an alternative medical opinion. On the other hand, a frank discussion of the relative likelihood of stone passage is important in helping the patient decide whether immediate intervention is appropriate. Since an accurate prediction of the time to spontaneous stone passage is very difficult, patients must understand that the quoted statistics on stone passage are largely based on trial periods of up to 4–6 weeks. In many cases, due to work and personal considerations and the uncertain nature of when a stone will pass, patients may opt for immediate definitive stone removal rather than a period of observation.

## Ureteroscopy

In performing URS, there are two basic choices of endoscopes: semirigid and flexible (see Chapters 39 and 40 and other chapters in this section). Semirigid instruments have fiber-optic bundles, range in size (external diameter) from 6.9 to 10 Fr, and may have single or dual working channels. There are several advantages associated with the use of semirigid ureteroscopes. In most cases, visualization is superior and it is easier for the operating urologist to control the instrument and manipulate accessory equipment such as baskets, graspers, etc. The diameters of the working channels of semirigid ureteroscopes are usually wider than those seen with flexible instruments, which allows for easier use of accessory equipment and improved irrigant flow. When removing stone fragments, repeated passage of the scope into the ureter is generally easier than when using a flexible instrument. In addition, semirigid instruments are often more durable than flexible instruments, leading to less breakage and lower cost associated with long-term use. Semirigid ureteroscopes are best suited for stones in the distal ureter (see Video 47.1) below the crossing iliac vessels and may be more difficult to pass proximally, especially in men with large prostates. Over the last few decades, these scopes have been made with narrower calibers and greater lengths to allow access to the proximal ureter, renal pelvis, and even parts of the calyceal system. Nevertheless, further technologic advancement of these rigid instruments (aside from incorporation of digital imaging systems) has slowed in recent years, as the utility of these scopes has reached a plateau [8]. The semirigid instrument is often easier for a single operating surgeon to use and usually allows for better visualization and irrigant flow. The semirigid scope is particularly well suited for patients who have an indwelling stent prior to URS as this leads to passive dilation of the ureter, thus making passage of the instrument easier. However, if resistance is encountered, the semirigid instrument should never be forced more proximally in the ureter and instead switching to a flexible instrument is advisable.

The greatest technologic advances in URS over the last several years have come in the area of flexible instruments. Initially, lack of durability of flexible ureteroscopes was a significant problem, and expensive and frequent need for repair was the norm in most busy endourologic practices [9]. However, improvements have been made and today's flexible instruments are generally less prone to breakage than earlier generations of scopes [10]. In addition, the degree of deflection (less important when treating ureteral stones than those in the kidney), size of the working channel, and overall visualization have also been significantly improved (see Video 47.2). A significant advance has been the development of fourth-generation digital flexible ureteroscopes [11]. Multescu et al. compared an Olympus digital ureteroscope and a standard Storz instrument and found that the digital scope had significantly greater maneuverability and visibility [11]. There was also less deflection loss with the digital scope when an accessory instrument was present in the working channel and irrigant flow was also superior. Furthermore, the light source for these digital scopes is dual light-emitting diodes (LEDs) at the tip, which essentially eliminates the risk of drape fire or patient burns in addition to lasting 10–20 times longer than the traditional fiber-optic scopes [12]. These digital scopes do have a slightly larger distal tip which houses "chip-on-the-tip" sensors to create improved imaging quality. A notable benefit of this is that an endoscope is no longer needed to attach to the scope on the proximal end, making the entire system lighter and easier to maneuver [13]. The digital scope's wider, and often more blunt, distal tip presents a potential disadvantage. Access to the ureter and passage through narrow segments of the upper urinary tract may be more difficult. In most cases, we have found that it is necessary to have a ureteral access sheath in place in order to pass the digital ureteroscope into the ureter, whereas the standard flexible scope can be passed, if desired, without this sheath. This observation is corroborated in a study of 157 ureteroscopies performed with either analogue fiber-optic scope or digital scope, which demonstrated significantly more cases performed with a digital scope that required ureteral access sheath (25 vs. 7.5%, $P = 0.0042$) [14].

In reality, semirigid and flexible ureteroscopes maintain complimentary roles in the treatment of ureteral stone disease: rigid instruments are better suited for distal ureteral stones while flexible scopes allow better access to the proximal ureter and intrarenal collecting system [15].

## Patient preparation and preoperative evaluation

Radiographic evaluation of the urinary tract is essential prior to URS and most patients will have undergone a noninfused computed tomography scan of the abdomen and pelvis [7]. Although no contrast is used with this study, the ureteral anatomy can usually be well defined. Additional information can be obtained at the time of the procedure by performing a retrograde pyelogram if necessary.

Some patients will initially present with urinary tract infection or urosepsis secondary to the obstructing ureteral calculus. This situation may be more commonly seen in patients with diabetes or those who are immunocompromised [16]. In this circumstance it is best to simply decompress the upper urinary tract with either ureteral stent placement or percutaneous nephrostomy tube insertion. Attempts to perform URS in the face of untreated or inadequately treated infection may lead to significant bacteremia with potentially disastrous complications. Even in patients without overt signs of infection or sepsis, clinicians should always perform urinalysis and consider urine culture to ensure any infection is adequately treated prior to URS [7].

Informed consent prior to URS should include a discussion of the risks of ureteral injury or perforation, as well as the risk of retreatment if the patient is not rendered stone-free. Although most injuries can be managed simply with stent placement alone, there are rare circumstances in which more extensive treatment may be necessary. In addition, the risks of ureteral stricture and the need for treatment of this complication should also be discussed.

## Surgical technique

URS is performed in most cases using general anesthesia. However, intravenous sedation alone or regional anesthetic techniques may be appropriate as clinical circumstances dictate. Allowance for adequate fluoroscopic visualization of the entire urinary tract is critical and provisions for radiographic monitoring should be made in all cases. In general, patients are placed in a dorsal lithotomy position with the contralateral lower extremity maximally abducted to facilitate access to the involved ureter. Patients without a urinary tract infection should be provided with 24 hours of antimicrobial prophylaxis per AUA best practice recommendations [17], with first-line treatment consisting of a fluoroquinolone or trimethoprim/sulfamethoxazole; alternative options include an aminoglycoside with or without ampicillin, a first- or second-generation cephalosporin, or amoxicillin/clavulanate. Patients with a history of urinary tract infection with organisms resistant to these first-line treatments should be offered culture-direct prophylaxis.

Increasingly, issues related to the use of anticoagulant medications prior to urologic surgical procedures have arisen. If such medications can be temporarily discontinued perioperatively with minimal risk to the patient, it is reasonable to do so if there is concern for potential bleeding. However, URS can be safely performed if necessary while patients remain anticoagulated so these medications should typically not be discontinued if nonurologic complications, such as to the cardiovascular system, could result from withholding them. Turna et al. retrospectively analyzed 37 patients undergoing flexible URS while on warfarin, clopidogrel, or aspirin, and compared them with a matched cohort of patients treated without anticoagulation [18]. No procedure had to be terminated due to poor visibility from bleeding and there was no significant difference in intraoperative or postoperative complications in the two groups.

All URS procedures should begin with surveillance of the bladder with particular attention paid to the location and configuration of the ureteral orifices. If the ureteral stone is readily visible at the expected location on initial fluoroscopic imaging, we generally do not perform a retrograde pyelogram initially since the injected contrast may obscure visualization of the stone or change its location. However, if the stone is not easily seen or there is a question regarding the ureteral anatomy, then it is best to perform a retrograde pyelogram to define the anatomy of the involved collecting system and ureter. The next step is passage of a wire past the stone and into the renal pelvis. A variety of guidewires are available, although we generally prefer a hydrophilic wire with a curved tip as this usually is the easiest to manipulate around the stone with minimal trauma to the ureter. Alternative wires with polytetrafluoroethylene (PTFE) coating allow more friction [19]. Once the wire is confirmed to be in the renal pelvis, a second guidewire may be placed as a safety wire. In the less common situation in which a wire cannot be passed proximal to the stone, the ureteroscope can be passed to the stone and then a wire can often be manipulated by the stone under direct visualization. If this is not possible, then careful fragmentation of the stone can be performed to free some space in the ureter alongside the stone and then the wire can be placed as early as possible. If a semirigid instrument is to be used, which is often preferable in the distal ureter, this can often be placed alongside the initial wire without the need for a second wire. If a flexible ureteroscope is to be used, this is generally passed over a wire or through a ureteral access sheath. In this case, the wire is usually removed after the scope is in position, so it is best to initially place a second wire as well that can be maintained throughout the procedure as a safety wire.

When passing the semirigid ureteroscope, it is important never to try to advance the instrument if visualization is limited or there is significant resistance, even if going over a guidewire. In most cases, active dilation of the ureter is not needed as the instruments are small enough to pass. However, in the presence of a stricture or in selected other cases, active dilation using a balloon dilation catheter or progressive dilators can be considered. Irrigation by an assistant using a hand-held syringe or other pumping device is often helpful to improve visualization; however, it is important to use this judiciously to avoid displacement of the stone more proximally. Pressure pumps are also available, although we prefer to use a hand-held syringe, which allows better control of the force with which the irrigant is delivered. Similar issues exist for the flexible ureteroscope, which is almost always passed initially over a wire to the level of the stone or through a ureteral sheath. As mentioned above, ureteral sheaths are available and are very helpful, particularly with flexible endoscopy, as they often facilitate passage of the instrument and allow for multiple insertions of the scope to remove fragments, etc. If difficulty is encountered in safely performing the procedure, it is always best to simply place a ureteral stent and allow for passive ureteral dilation, which generally makes a secondary URS procedure much easier to perform at a later date.

## Stone fragmentation and removal (see Video 47.1)

Once the ureteroscope has been successfully advanced to the level of a ureteral stone, a decision needs to be made whether to try and remove it intact or fragment the calculus. In previous years, when larger instruments were routinely used and the ureter was frequently dilated with a balloon or by another method, it was more common to remove stones intact. However, the advent of smaller scopes that may be passed without active dilation has made it more difficult to directly extract larger stones without risking damage to the ureter. As a general rule, when in doubt about whether a stone can be successfully removed without fragmentation, it is best to err on the side of caution and break it into pieces prior to removal. The two most commonly used methods to fragment ureteral stones are laser lithotripsy and pneumatic lithotripsy. The holmium:YAG end-fire laser is used commonly and offers several advantages in stone fragmentation. First, it can be used to fragment all stones irrespective of composition or hardness using narrow fibers of 200–365 μm in diameter. Second, the smaller fibers can be easily passed through flexible endoscopes with limited effect on the ability to provide irrigation to ensure adequate visualization. When working in the ureter, there is no significant concern about limitations in the ability to deflect the instrument as may occur when dealing with renal stones, particularly those in the lower calyces. Another advantage is the ability to ablate the stone, converting it to dust particles that do not have to be actively removed. The main disadvantage of the holmium:YAG laser is the associated cost of the instrument itself and of the disposable fibers.

Pneumatic lithotripsy most commonly involves the use of the Lithoclast device. This instrument is also highly effective in fragmenting stones and is generally associated with lower costs than those seen with the holmium:YAG laser as nondisposable probes are available. Disadvantages of pneumatic lithotripsy include the rigid probes which cannot be used with a flexible ureteroscope and the increased risk of retrograde stone propulsion. Garg et al. compared laser and pneumatic lithotripsy for ureteral stones in a randomized, prospective study and found that both methods were safe and effective [20]. However, the immediate stone clearance rate was significantly better in the laser group and stone migration occurred in 16% of cases using the pneumatic device. Similar results when comparing laser and pneumatic lithotripsy in treating ureteral stones were reported by Maghsoudi et al. [21].

Once the stone has been adequately fragmented, or if it is to be removed intact, a variety of devices can be used for stone retrieval. Stone baskets are available in a variety of shapes and configurations, and personal preference and experience are important in selecting which to use. In most cases, our preference is a tipless, nitinol basket when using the flexible instrument, and stone graspers with a rigid instrument. The advantage of the graspers is that the stone can be more easily disengaged if it is too large to remove and it will generally fall out of the graspers before significant damage to the ureter can occur. The baskets hold the stones more securely, but if the size of the calculus has been misjudged, it may be more difficult to disengage the stone from the basket for further fragmentation. In addition, the ureter can be damaged as the stone and basket are pulled distally if too much force is applied.

Another decision that needs to be made after the stone has been fragmented in the ureter is whether to try and remove all the fragments during the procedure or to allow them to pass later. It is generally our practice to remove all fragments from the ureter and this approach is supported by the literature [22, 23]. Schatloff et al. randomized 60 patients undergoing URS with laser lithotripsy to intraoperative fragment retrieval or spontaneous fragment expulsion, and found a significantly higher rate of unplanned medical visits in the group with incomplete fragment extraction. In addition, there was a trend towards higher rates of rehospitalization, residual stones, and the need for ancillary procedures in this group [22]. A report by the EDGE Consortium [23] found that residual fragments larger than 4 mm in size were independently associated with re-intervention compared to smaller residual fragments when controlling for other patient and operative factors. When directly comparing dusting versus basketing techniques, dusting resulted in a shorter median time to re-intervention. However, the technique was not independently associated with re-intervention on multivariable analysis.

The role of postoperative stenting after ureteroscopic stone removal is controversial and will be addressed in Chapter 55.

When performing ureteroscopic stone removal, prevention of inadvertent retrograde calculus migration is important in achieving a successful outcome. This is particularly true when using a semirigid instrument since it may not be possible to advance the scope further proximally in the ureter or renal pelvis to reach the stone if it has been displaced. In some situations, a flexible ureteroscope may not be available and some surgeons may not be comfortable performing flexible endoscopy. A variety of approaches are available to help avoid stone retropulsion. First, when using the holmium:YAG laser to fragment the stone, we try to place the fiber on top of the stone rather than on the most distal portion, so that the energy delivered to the calculus is less likely to push it more proximally. Second, some semirigid instruments have two working channels which allow the stone to be engaged in a basket placed through one channel while the laser fiber or pneumatic probe is placed through the other channel. In addition, baskets that can accommodate a laser fiber to be placed through them are also available. Third, instillation of lidocaine jelly proximal to the stone appears to help prevent retropulsion [24]. Zehri et al. used a 5 Fr ureteral catheter advanced beyond the stone to instill 2 ml of lidocaine jelly. Semirigid URS was then performed and the stones were fragmented using a pneumatic lithotripsy device. When comparing groups using lidocaine jelly and a randomized control group treated without, there was significantly less proximal stone migration and a better stone-free rate at 2 weeks in those receiving lidocaine [24]. Finally, a variety of antiretropulsion disposable devices are available [25–29]. In general, these devices are placed proximal to the stone and are then deployed in a configuration that prevents stone migration as fragmentation occurs. They may also help in removal of stone fragments as they are pulled distally after fragmentation is completed. Reduction in stone retropulsion using these devices has been demonstrated both *in vitro* and in clinical assessments [25–29]. The primary disadvantage of these antiretropulsion devices are the associated cost. One study estimated that antiretropulsion devices are cost-effective if the rate of retropulsion is above 6.3% [30]. Overall, when a flexible ureteroscope is available and the operating surgeon is comfortable and experienced with its use in the proximal ureter and kidney, stone migration is a minor concern and can usually be avoided with simple measures as described above. However, if semirigid URS is the only available option, then retropulsion is a greater concern since there is a risk that the procedure will not be completed successfully, leading to the need for secondary approaches, such as extracorporeal shock-wave lithotripsy, if the stone moves into the proximal ureter or kidney before it is adequately fragmented. In such circumstances, extra efforts to avoid stone migration, such as the use of retropulsion devices, may be appropriate.

## Complications

Advances in fiber-optic technology and the availability of smaller and flexible instruments have led to an overall improvement in the safety of ureteroscopic stone removal. However, complications may still occur due to mucosal injury from the endoscope itself or from the use of lithotripters to fragment stones within the ureter. The most common complication is ureteral perforation or the development of a false passage in the ureter. In general, this should be easily recognized at the time of the occurrence or when a retrograde pyelogram is performed at the completion of the procedure. As long as a safety wire is left in place, minor perforations generally are easily managed by the placement of a ureteral stent which is left in place for up to 4–6 weeks depending upon the extent of the injury. There is an increased risk for the development of ureteral strictures after perforation has occurred, so imaging 6–12 weeks after the stent is removed is essential in these cases, even if the patient is asymptomatic [31]. If a stent cannot be placed or if the injury is more extensive, then a percutaneous nephrostomy tube may be placed.

Overall, the incidence of strictures following ureteroscopic stone removal is 1–2% [31, 32]. In addition to ureteral injury, the extent and duration of stone impaction may increase the risk of stricture formation. Some authors have recommended routine imaging following stone removal since silent obstruction may occur. Weizer et al. reported that seven of 459 patients undergoing ureteroscopic stone removal were asymptomatic despite the development of ureteral strictures [32]. Therefore, they recommended that all patients undergo imaging of the upper urinary tract within 3 months after stone removal. Adiyat et al. investigated the need for routine postoperative imaging in 253 patients undergoing ureteroscopic stone removal [31]. While the overall incidence of stricture formation in this group was 1.4%, none of 158 patients with uncomplicated procedures developed strictures. Patients with complications were defined as those with ureteral perforation, stone impaction, or the need for balloon dilation of the ureter. Therefore, these investigators concluded that routine follow-up imaging is not essential after uncomplicated URS.

The most serious complication of ureteroscopic stone removal is ureteral avulsion, which fortunately is a rare occurrence. Ureteral avulsion most often results from trying to pull a stone that is too large to be removed intact down the ureter in a basket. The treatment of ureteral avulsion depends on the extent and location of the injury. If the distal ureter is the site of injury, avulsion can be managed by ureteral reimplantation with the use of a psoas hitch or Boari flap. For injuries that occur in the mid or proximal ureter, management can be quite challenging and may require ureteral substitution, autotransplantation of the kidney, or even nephrectomy. Surgery is best performed immediately to avoid the development of edema and inflammation, which can hamper a successful outcome. If a delay in treatment is necessary, then a nephrostomy tube should be placed.

## Conclusions

Ureteroscopic stone removal has become the procedure of choice for most patients with ureteral stones. With modern fiber-optic technology, the availability of effective lithotripsy devices, such as the holmium:YAG laser and pneumatic devices, and flexible endoscopes, the success rate in removing ureteral stones at all levels of the ureter is excellent. Issues related to stone migration can be effectively managed using a variety of techniques and disposable devices that are readily available, allowing for a minimal risk of the need for secondary procedures to remove stones. Overall, ureteroscopic stone removal is highly effective, with a low risk of complications, and it can be performed successfully and safely by most urologists.

## Introduction

During the past three decades, the surgical management of kidney stones has undergone many technological advances and one is the development of the flexible ureteroscopy (fURS). The development of this technique as well as ancillary equipment such as baskets, graspers, and others, and improvements in lithotripsy with holmium:YAG lasers, have led to the expansion of its indications to diagnostic and therapeutic management of medical issues of the upper urinary tract such as urolithiasis and urothelial tumors.

First described in 1964 by Marshall, the flexible ureteroscope did not gain popularity since it was only passively deflectable and did not include a working channel. Although the first successful procedure using fURS with active deflection in humans was reported by Takayasu, it was not until 1987 that Demetrius Bagley introduced fURS as we know it today [1–5]. At this time, the fURS suffered from poor resolution, low angle of deflection, difficult ureteral insertion, and, until 1974, lack of irrigation [3]. But this instrument benefited from many advancements in the 1980s, including fiber-optic bundles for light transmission and image relay, reduction of the outer diameter, passive and active deflection in upward and downward directions, and addition of a working channel. One of the latest developments was the introduction of a digital imaging system which has improved the image quality substantially. Currently, we can distinguish two types of fURS: fiber-optic and digital fURS. The difference between these two endoscopes is the light transmission and image relay. In fiber-optic scopes, light and image are transmitted in analogue format through fiber-optic cable whereas the illumination in digital scopes is produced made by fiber-optics or by a light-emitting diode (LED) and image capture is via a digital sensor located at the distal end of the endoscope: either a complementary metal oxide semiconductor (CMOS) or charge-coupled device (CCD). In both cases, most manufacturers have models with a working channel of 3.6 Fr (for irrigation and the use of accessory instruments) and at least one 270° active deflection of the tip. The most recent development in fURS was the introduction of single-use digital fURS [6, 7].

Due to these technological advances, fURS has gained in popularity and has become the treatment of choice for kidney stones.

## Indications

The different treatment modalities offered to patients with kidney stones are:

- extracorporeal shock-wave lithotripsy (ESWL),
- fURS,
- percutaneous nephrolithotomy (PCNL): conventional and miniaturized PCNL (mini-PCNL, ultramini-PCNL, micro-PCNL),
- open surgical and laparoscopic removal.

In case of suspected cystine or uric acid stones, ESWL is not an option because cystine stones are often only faintly radiopaque and pure uric acid stones are typically radiolucent. Furthermore, cystine stones are typically resistant to ESWL fragmentation.

According to the European Association of Urology (EAU) guidelines, the indications for active stone removal of renal stones are stone growth, stones in high-risk patients for stone formation, obstruction caused by stones, infection, symptomatic stones (e.g. pain or hematuria), stones

>15 mm, stones <15 mm if observation is not the option of choice, patient preference, comorbidity, social situation of the patient (e.g. profession or traveling), and choice of treatment [8].

Once the choice of stone removal is taken, the choice of the treatment modality depends on several stone characteristics, such as size, location, composition (if available), collecting system anatomy. Other factors include complication rate, patient comorbidities, patient preference, available technical equipment, and economic aspects.

Both the American Urological Association (AUA) and EAU provide recommendations for the selection of procedure for active removal of kidney stones [8–10].

## AUA guidelines

The latest recommendations of the AUA about the surgical treatment of kidney stones were published in 2016 [9, 10]. ESWL, fURS, and PCNL are the treatment options for symptomatic patients with <20 mm non-lower pole renal stones. AUA guidelines recommend ESWL or fURS as first-line treatment for such stones because their stone-free rates are acceptable and have lower morbidity than PCNL.

For symptomatic ≤10 mm lower pole kidney stones, ESWL or fURS are the two options that urologists should offer. However, patients with a skin-to-stone distance greater than 9–10 cm or stone attenuation greater than 900–1000 Hounsfield units have less successful results with ESWL. An endoscopic approach (fURS or PCNL) is recommended for 10–20 mm lower pole renal stones because they appear to be less affected by stone burden than ESWL.

For stones >20 mm, PCNL is recommended as first-line option because it offers a higher stone-free rate than ESWL or fURS and is less invasive than open surgery or laparoscopic/robot-assisted procedures. PCNL should also be the first treatment utilized for most patients with staghorn calculi.

fURS should be offered as first-line therapy in most patients who require active stone removal with uncorrected bleeding diatheses or who require continuous anticoagulation/antiplatelet therapy.

The recommendations are summarized in Tables 48.1 and 48.2.

**Table 48.1** AUA treatment algorithm for renal calculi (<20 mm lower pole renal calculi excluded).

| Kidney stone (<20 mm lower pole stone excluded) | |
|---|---|
| <20 mm | ESWL or fURS |
| >20 mm | PCNL |

## EAU guidelines

The latest recommendations of the EAU about the surgical treatment of kidney stones were published in 2018 [8]. ESWL and fURS are the first-line treatment for renal stones <10 mm. For 10–20 mm non-lower pole renal stones, ESWL, fURS, and PCNL are the treatment modalities that clinicians should offer. For 10–20 mm lower pole renal stones, PCNL or fURS is recommended in cases of unfavorable factors for ESWL, because then its efficacy is limited. With favorable factors for ESWL, ESWL or an endoscopic approach (fURS or PCNL) should be offered. Unfavourable factors for ESWL are shock-wave-resistant stones (calcium oxalate monohydrate, brushite, or cystine), steep infundibular-pelvic angle, long lower pole calyx (>10 mm), and narrow infundibulum (<5 mm).

Kidney stones greater than 20 mm should be treated by PCNL as a first-line option because it offers a higher stone-free rate than ESWL or fURS. In cases where PCNL is not an option or contraindicated, renal stones >20 mm may be treated with fURS. However, in such cases there is a higher risk of staged procedures and placement of a ureteral stent may be needed.

In case of an uncorrected bleeding disorder or continued antithrombotic therapy, fURS, in contrast to ESWL and PCNL, might offer an alternative approach since it is associated with lower morbidity.

The recommendations are summarized in Tables 48.3 and 48.4.

**Table 48.2** AUA treatment algorithm for <20 mm lower pole renal calculi.

## Contraindications

There are no specific contraindications to performing fURS apart from general problems such as general anesthesia or untreated preoperative positive urinalysis.

## Technique

### Patient positioning, anesthesia

The patient is placed in lithotomy position. Although local, spinal anesthesia and intravenous sedation are feasible, fURS is mostly performed under general anesthesia. General anesthesia is suggested because it offers some advantages: renal movement caused by respiration may affect renal navigation and lithotripsy whereas with mechanical ventilation the use of apnea stops this problem temporarily [11–13].

### Access to the upper urinary tract and ureteral access sheath placement

The procedure begins with rigid cystoscopy to look for the location and configuration of the ureteral orifices. The next step is the placement of a guidewire into the renal pelvis. The choice of guidewire depends on surgeon preference; however, we prefer to use a stiff hydrophilic guidewire. Some authors have reported the feasibility of performing fURS in the absence of a working or a safety guidewire without intraoperative complications [14–18]. However, we think the use of a safety guidewire is still useful as it does not increase morbidity, ensures access to the collecting system, and facilitates the placement of a stent in cases of ureteric or collecting system injury such as ureteral perforation or excessive bleeding. Alternatively, the procedure may begin directly with first-look semirigid ureteroscopy, always using a safety guidewire, which has the advantage of passively dilating the whole ureter in order to choose the most appropriate ureteral access sheath (UAS) size [19]. Once the guidewire has been placed – with or without performing semirigid ureteroscopy – the flexible ureteroscope may be passed up to the kidney alongside this safety guidewire or over a second guidewire (inserted using a dual-lumen catheter) under fluoroscopic guidance. The other option is to place a UAS under fluoroscopic control and insert the flexible ureteroscope through the UAS. These different options for endoscope insertion depend on stone burden, upper urinary tract anatomy, and the surgeon's preference.

The goals of using a UAS are to facilitate multiple passages for stone fragment removal, to protect the endoscope, and, most importantly, to provide irrigation with better fluid outflow, thereby decreasing the intrarenal pressure [2, 20–23]. The choice of the UAS, its size, and its diameter depend on patient anatomy, the endoscope used, and surgeon preference [24, 25]. Instead of using two guidewires, some new designs of UAS use only one guidewire, meaning that the working guidewire turns into safety guidewire [26, 27] (Figure 48.1). Attention has to be paid to the force applied during UAS placement because ureteral lesions may be the consequence of forced maneuvers. Furthermore, in cases that require a second procedure, any stone fragments that may have migrated into the ureter have to be removed

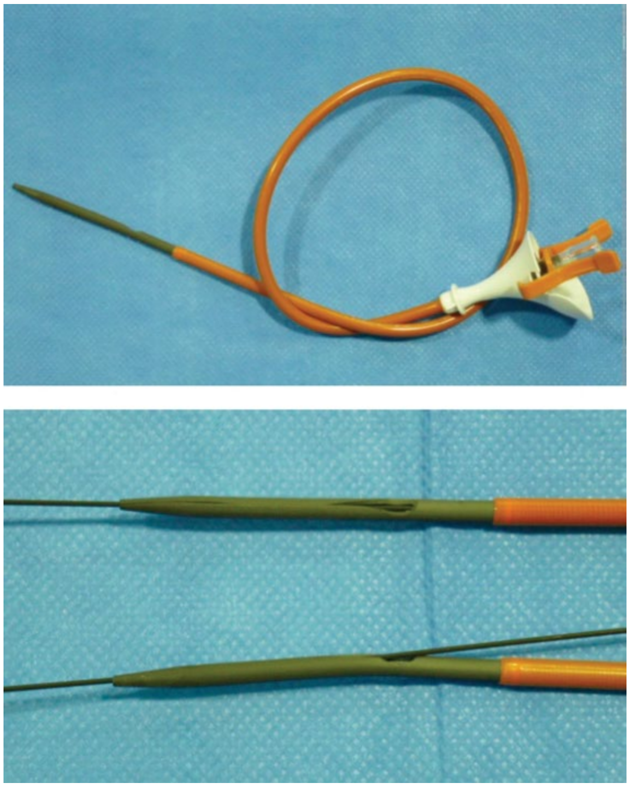

**Figure 48.1** Ureteral access sheath. The removal of the inner tip automatically converts the working guidewire as a safety guidewire lateral to the sheath.

before UAS insertion. If any resistance is encountered during UAS placement, it latter should be stopped and the endoscope introduced to explore the ureter. If not possible, it is safer to place a ureteral stent for passive ureteral dilation, making a secondary fURS procedure much easier to perform at a later date. The best position for the UAS is with its tip in the proximal ureter or just below the ureteropelvic junction but not through it, since this is the portion of the ureter at greatest risk of avulsion because it has the least muscular tissue support.

Once the flexible ureteroscope is placed in the kidney, the collecting system is explored starting with the upper calices followed by the middle and lower calices. In the right kidney, the calyces are seen on the left of the endoscope screen. Thus, supination is the essential movement for exploring the right renal cavities. Conversely, the left renal calyces are seen on the right of the endoscope screen, meaning that pronation is essential when exploring the left kidney (Figure 48.2).

## Lithotripsy and fragment extraction

Laser lithotripsy, using holmium:yttrium-aluminum-garnet (Ho:YAG) laser and a laser fiber, has become the standard for stone lithotripsy during fURS procedures as it has proven efficacy and safety [28]. It delivers a pulsatile energy and operates at a wavelength of 2100 nm, which is in the infrared spectrum and invisible to the human eye. The holmium laser is effective for all types of stone composition. Stones are ablated by a photothermal effect whereby long laser pulses (100–1000 microseconds) induce a temperature rise inside the stone. Laser radiation is absorbed by residual water in the stone, creating a vapour pressure that breaks the stone [29–31].

The majority of laser lithotripters allow the urologist to control two parameters: the pulse energy and pulse frequency (Figure 48.3). The total power output results from the product of these two parameters: total power (W) = pulse energy (J) × pulse frequency (Hz). By adjusting these parameters, the urologist decides the energy intensity that is delivered at the tip of the laser fiber to ablate the stone. In the new generation of laser lithotripters, a third parameter can be set: pulse duration. The laser machine allows a choice between short-pulse and long-pulse modes (Figure 48.3). The difference between these two modes is that, for a same amount of energy, its distribution is over a short (180–330 microseconds) or a longer period of time (650–1215 microseconds) [32]. At the same power level, high-frequency/low-pulse-energy is less efficient than low-frequency/high-pulse-energy lithotripsy. Stone ablation volume directly correlates with pulse energy, whereas frequency, especially high frequency, and total power setting play more minor roles [33]. An *in vitro* study showed that the short-pulse mode is 25.0 and 9.9% more ablative than the long-pulse mode

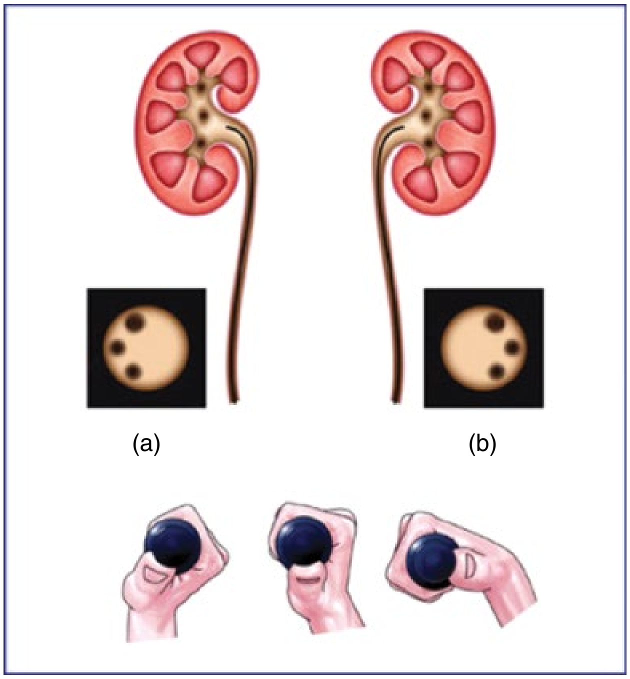

Figure 48.2 Dominant-hand pronation and supination to change the direction of the distal tip of the scope. (a) Supination is essential when the scope is in the right renal cavities and (b) pronation is essential when the flexible ureteroscope is in the left renal cavities.

Figure 48.3 Laser parameters.

when associated with low frequency/high pulse energy and high frequency/low pulse energy, respectively [32–34]. Low pulse energy, like high-frequency/low-pulse-energy settings, produces smaller stone fragments (also called the "dusting effect") than high-pulse energy, such as low-frequency/high-pulse-energy settings [35–37].

Thus, there are two options for stone laser lithotripsy. The first is dusting, where the stone is reduced to fine dust and to small fragments of 2 mm or less in diameter which are supposed to pass spontaneously, avoiding the use of a basket. Second, stone fragmentation produces stone pieces that subsequently have to be removed individually with a basket [35–38] (Figure 48.4). Dusting lithotripsy requires the surgeon to work over the stone's surface and avoid always being in contact at the same place by "painting" with the laser fiber [38]. If fragmentation is performed and a 10/12 Fr UAS is used, for example, the stones have to be reduced to 3 mm fragments, which is the maximum stone size that can be removed through this type of sheath. The removal of such fragments is time-consuming and may require a specific laser lithotripsy technique called the "popcorn effect" to reduce the stone burden, thereby avoiding numerous back-and-forth movements with the basket [33, 39]. Each method has its advantages and disadvantages, but surgeon preference, stone size, composition, location, and intrarenal anatomy determine which ablative technique is the most appropriate. Furthermore, the two techniques can be combined by starting with dusting and finishing with fragmentation to obtain stone pieces for stone analysis. For large stones, fragmentation alone will produce a multitude of small fragments the removal of which may be time-consuming. Conversely, complete dusting of such stones may also increase operative time. Thus, both techniques may be used for large stones as well as utilizing the popcorn effect when significant stone pieces are remaining at the end of the procedure to avoid the extraction by basket of all the fragments.

The different laser settings for stone lithotripsy are:

- fragmentation: high energy (1–2 J), low frequency (3–5 Hz), and, if needed, short pulse duration,
- dusting: low energy (0.2–0.5 J), high frequency (10–20 Hz), and, if needed, long pulse duration,
- popcorn effect: high energy (1 J), high frequency (10–20 Hz), and, if needed, long pulse duration.

Another parameter that may facilitate laser lithotripsy is the influence of the working channel position. Most flexible ureteroscopes have a 3 or 9 o'clock working channel position. When performing laser lithotripsy in a

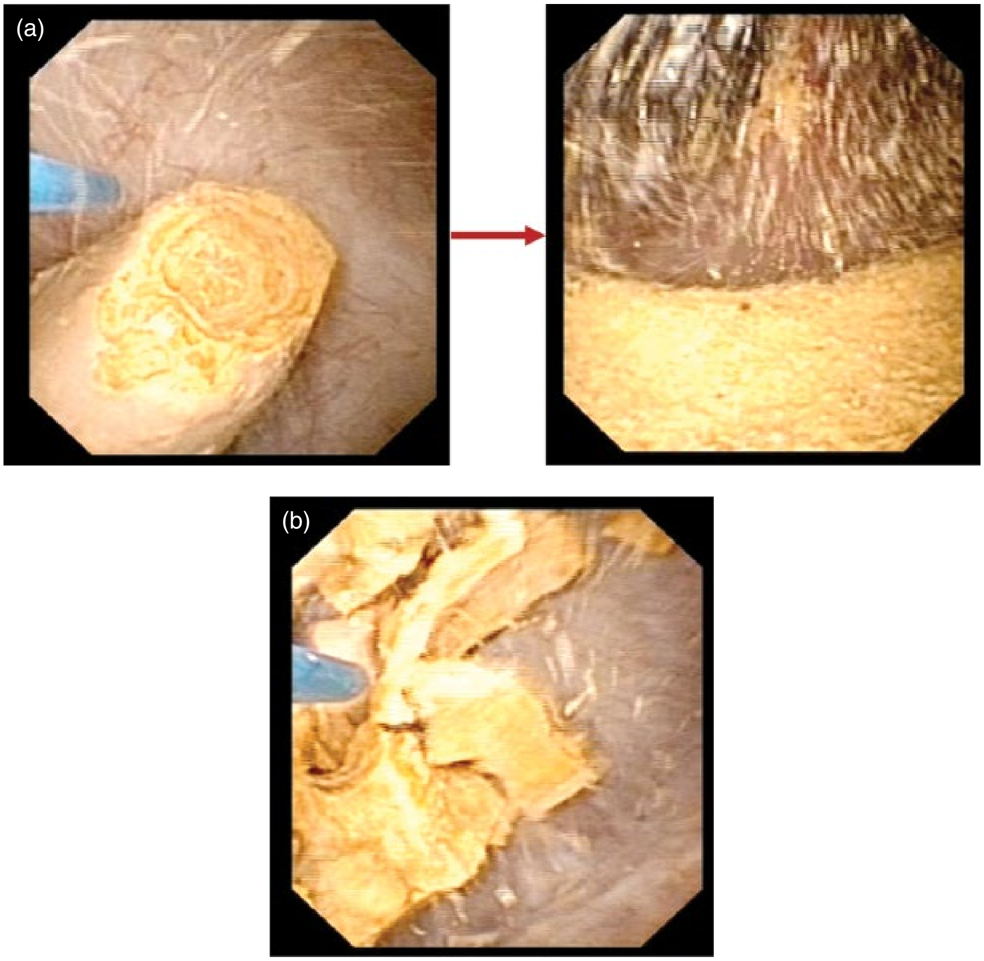

**Figure 48.4** Laser lithotripsy. (a) Dusting effect; (b) fragmentation.

right kidney, a 3 o'clock position is better to ablate stones. However, to better fragment stones located in right anterior calyces, a 9 o'clock working channel position is advised. Conversely, a 9 o'clock working channel is advised for left renal stones except for posterior calyces where a 3 o'clock working channel is preferable (Figure 48.5).

The last parameter to take into account is the laser fiber diameter. Large fibers (550 μm) produce wider fissures, while small fibers (200 μm) create deep fissures, but neither surpasses the other in terms of ablation volume [33, 34]. Although large-diameter laser fibers are more resistant to fiber-tip degradation or the "burn-back" effect, their stiffness reduces ureteroscope maximal deflection and their diameter decreases irrigation flow. Conversely, small-diameter laser fibers are more fragile and prone to fiber-tip degradation, but this is compensated for by better irrigation, better endoscope deflection, and less retropulsion [33, 40, 41].

Finally, when stone removal has to be performed, tipless nitinol baskets have become the standard devices and many designs are available on the market (Figure 48.6). The advantages of nitinol baskets are their flexibility and ability to not damage the scope and intrarenal cavities during fragment extraction. A diameter smaller than 2.2 Fr allows maximum irrigation flow and deflection of the endoscope, whereby all parts of the collecting system can be reached [41]. Using a basket blind has to be avoided as it may increase the risk of ureteral avulsion. Thus, stone retrieval with baskets, even if a UAS is used, has to be guided endoscopically. The stone and basket have to be kept under direct vision as they are removed; the size of the stone is continually compared with the size of the ureteral lumen until entry into the

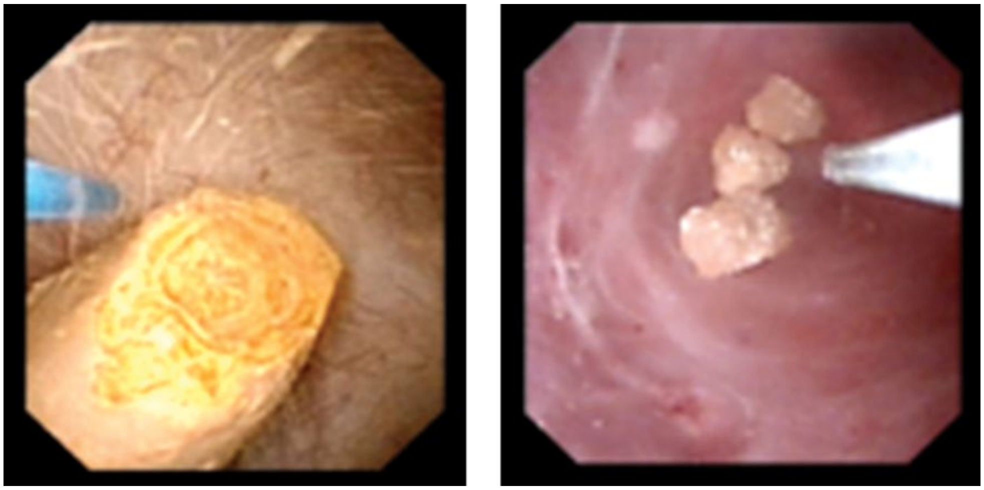

**Figure 48.5** Working channel position. Left: 9 o'clock working channel, Right: 3 o'clock working channel.

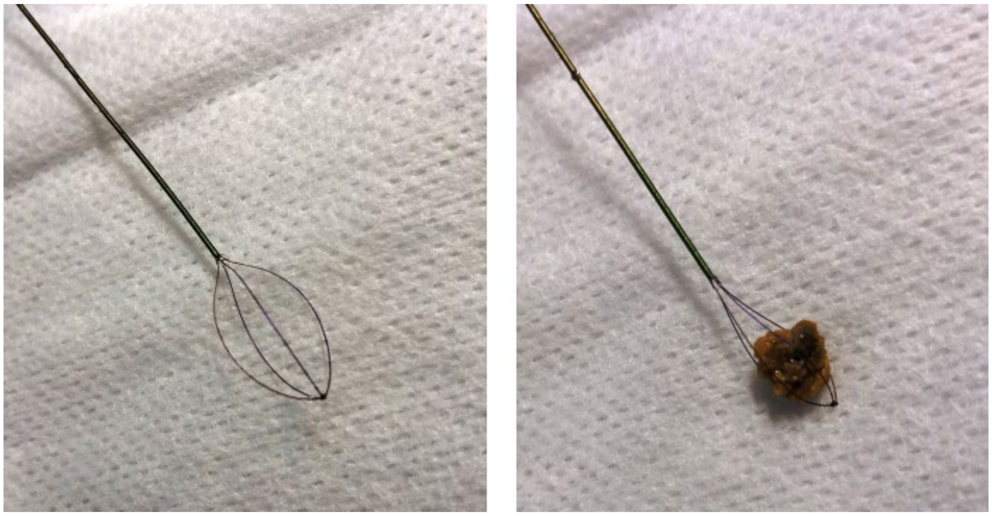

**Figure 48.6** Examples of nitinol baskets.

sheath, if used. If the stone appears to be too large to be removed intact, it should be fragmented into smaller pieces that may subsequently be removed [42].

Although fURS is often performed with continuous saline irrigation through the working channel, an additional device such as a syringe or manual hand pump may be needed to improve visibility when an instrument is inserted into the working channel, while dusting a stone, or of minor venous bleeding occurs. Furthermore, these devices may be helpful to flush stone fragments to facilitate basketing in difficult cases. However, although irrigation pressure devices are helpful and often used, there is a risk of increased intrarenal pressure. While working in the renal cavities for a long time, placing a UAS may prevent the elevation of pressure (Figure 48.7).

## Lower pole stones

When considering lower pole stones, the surgeon should attempt to relocate the stone with a nitinol basket to a more favorable position (upper pole or renal pelvis) [43] (Figure 48.8). This practice reduces the risk of damage to the ureteroscope and makes stone targeting during laser lithotripsy easier and more effective. Furthermore, according to the stone lithotripsy technique used, the stone fragments produced will be easier to grasp with the basket or able to pass spontaneously through the ureter instead of accumulating in the lower pole. However, stones larger than 10 mm may not be possible to grasp and relocate, necessitating laser treatment *in situ*, with the ureteroscope maximally deflected, potentially increasing the risk of laser fiber failure and ureteroscope damage [44]. In that case, it is recommended to insert the laser fiber with the minimal deflection of the endoscope to avoid any working channel damage and subsequently access the lower pole to treat the stone *in situ*. However, once the laser fiber is in place, this results in a loss of the flexible ureteroscope's maximal angle of deflection and access to the lower pole may be difficult [41, 45].

For this reason a new design of laser fibers with a ball-tip shape has been developed, which reduce friction within the working channel in a completely deflected ureteroscope, thereby reducing the likelihood of endoscope damage [46]. However, after the first minute of laser emission, the ball-shaped tip fibers lose their special feature due to fiber-tip degradation, especially at high pulse energies [47]. Thus, this allows the insertion of a ball-tip fiber only once in a fully deflected flexible ureteroscope. A recent study reported that cleaving the tip of standard laser fibers with metal scissors results in

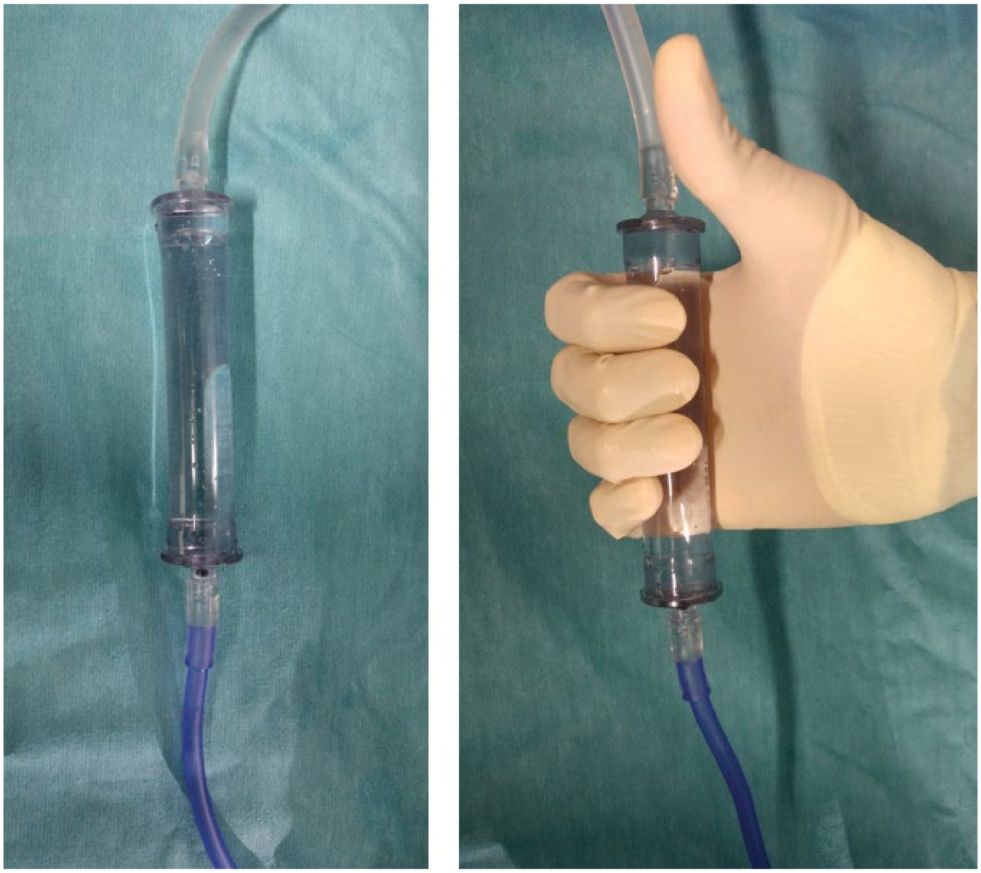

**Figure 48.7** Hand-assisted irrigation device.

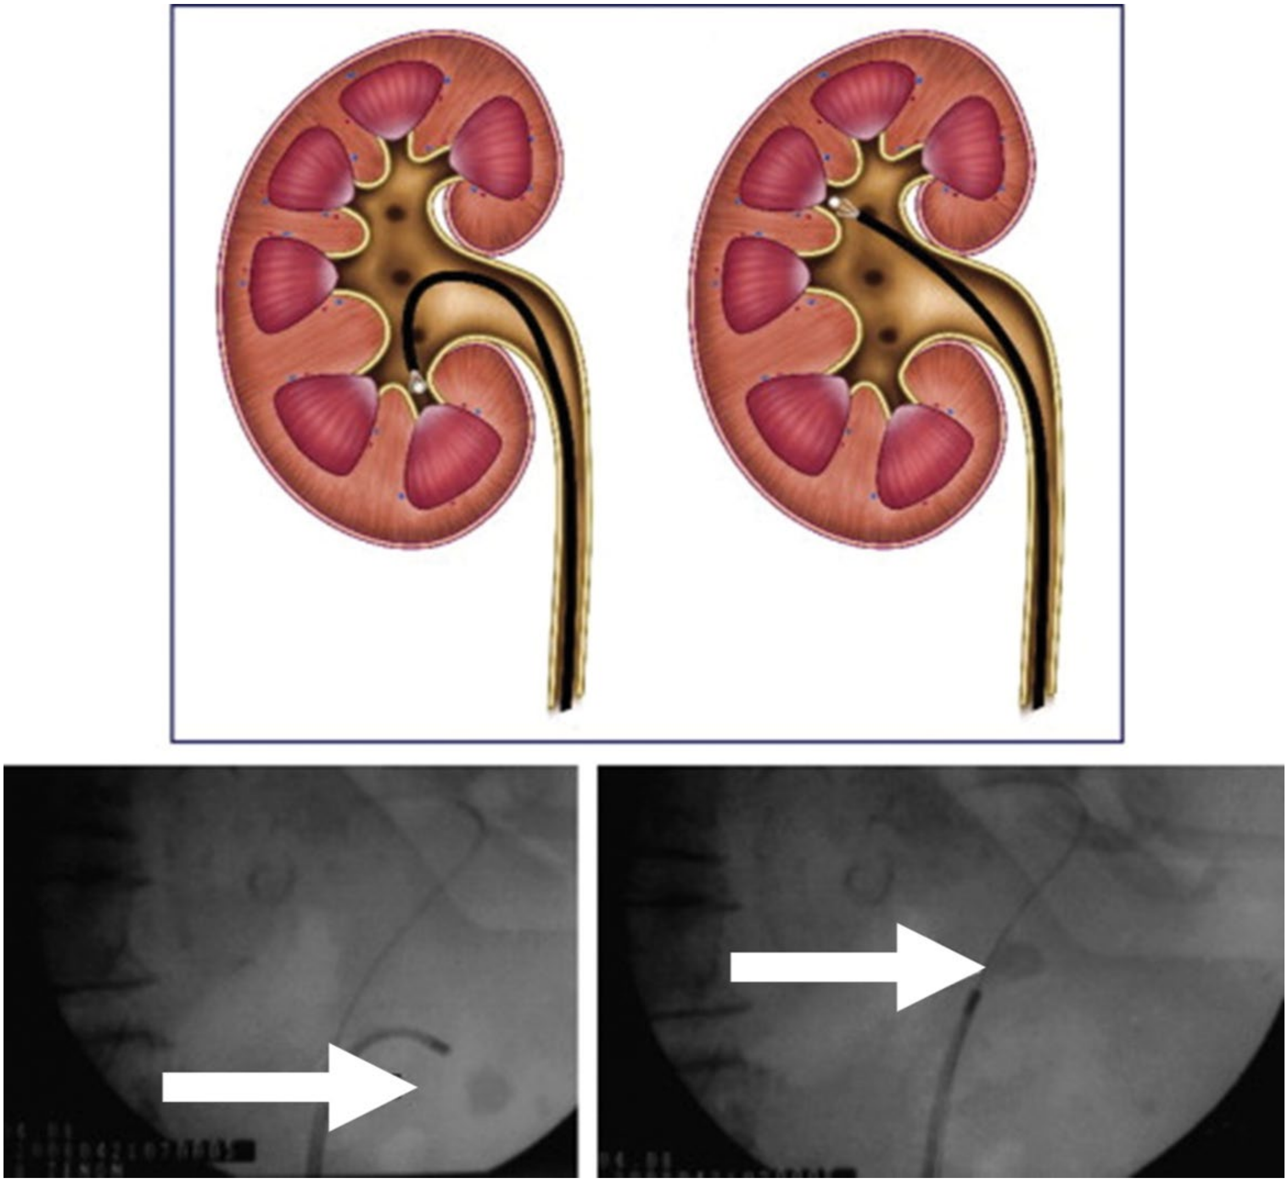

**Figure 48.8** Relocation of a lower pole renal stone.

equivalent passage capabilities through a deflected endoscope to ball-tip-shaped fibers [45]. Recent work also showed that laser fiber diameter and curve as well as laser settings are parameters to take into account when treating a lower pole renal stone *in situ* [48]. The 272 μm fibers broke at the curve diameter of 9 mm and below when using dusting parameters (high frequency and low energy) and at 12 mm when using fragmentation parameters (low frequency and high energy). The 365 μm fibers broke at 9 mm for dusting and required a smaller curve (15 mm) to break under fragmentation parameters. Thus, to prevent laser fiber breakage, it is advised to use small 272 μm fibers, with dusting parameters, to reduce the stone diameter. It can then be relocated as soon as possible.

## Calyceal diverticulum

In cases of calyceal diverticulum the procedure begins as standard fURS. Once the endoscope is placed into the renal cavities, the principle consists of injecting contrast through the working channel to identify the diverticular neck with the assistance of fluoroscopic guidance (Figure 48.9a,b). In difficult cases, the blue test technique has been suggested (Figure 48.9c). Instead of injecting contrast alone, a mix of contrast and methylene blue or indigo carmin is injected. If opacification of the diverticulum is obtained, this means that its neck is patent. Then, the collecting system has to be washed out using the saline irrigant through a manual irrigation device.

| step 7 |  | Exploration of the cavities and identification of the leakage of the indigo carmin by diverticular neck |
| step 8 |  | Introduction of the laser and incision of the neck<br>Local fragmentation of the calculi and marsupialization |

**Figure 48.9** (a) Diverticulum at the middle portion (arrow). (b) Flexible ureteroscope at the diverticulum. (c) Blue test technique. Retrograde pyelography.

Once the cavities are clear, a leakage of blue by the diverticular neck is identifiable. The next step is laser incision of the diverticular neck and subsequent treatment of the stone burden [49].

### The use of apnea during laser lithotripsy

Laser lithotripsy of renal stones and precise laser ablation (upper tract urothelial carcinomas, endopyelotomy, incision of diverticular neck, stone in narrow calyx) are made challenging by the renal movement caused by respiration and diaphragmatic excursion. The surgeon has to treat a moving target without injuring the urothelium or papillae. For these reasons, apnea may be needed during fURS to facilitate treatment. A recent report described a protocol to perform apnea during fURS, allowing its maintenance for approximately 5 minutes. This illustrates the role of the collaboration between anesthesiologists and surgeons in order to achieve optimum treatment [13].

### Ureteral stenting

Careful ureteral exploration should be performed at the end of the procedure to retrieve the scope and the UAS while keeping the scope's tip a few centimeters out of the sheath to detect eventual ureteral lesions due to UAS placement and stone fragments [50].

To prevent the incidence of postoperative ureteric obstruction and renal colic secondary to ureteral edema, a ureteral stent may be placed. This stent placement has also been advocated to facilitate the passage of stone fragments secondary to passive ureteric dilation [51–55]. Although this common practice is still debated, it has been reported in large series that approximately 80% of urologists place a ureteric stent after uncomplicated ureteroscopy for stone disease [56–64]. The last AUA guidelines recommended ureteral stenting among patients with ureteric injury during URS, those with evidence of ureteral stricture or other anatomical impediments to stone fragment clearance, such as ureteral wall edema, a large stone burden (>15 mm), those who have an anatomically or functionally solitary kidney or renal functional impairment, and in those in whom another ipsilateral URS is planned [9, 10].

## Outcomes

The assessment of outcomes after renal stone treatment is always challenging because many parameters are variable. First of all the technique employed may vary. Secondly, the definition of the stone-free status depends on the imaging modality used, which is often evaluated in a different way in each study, and the cut-off used for insignificant fragments. And finally, most of the studies have a retrospective design, which may limit their strength.

A recent retrospective study compared the stone-free rates, defined as residual fragments up to a maximum of 2 mm in diameter detected on ultrasound or computed tomography scan at 1 month follow-up, between four stone size categories: ≤10 mm, >10 and ≤20 mm, >20 and ≤30 mm, and >30 mm. The authors found 90.4%, 79.8%, 70.5%, and 55% stone-free rates after one fURS procedure for the ≤10 mm, >10 and ≤20 mm, >20 and ≤30 mm, and >30 mm groups, respectively [19].

### Renal stones (<20 mm)

For <20 mm non-lower pole renal stones, PCNL stone-free rates are the least affected by stone size, while stone-free rates of ESWL and fURS decline with increasing stone burden [9, 10, 65]. However, stone-free rates of ESWL and fURS are acceptable and show less morbidity than PCNL. Compared to ESWL, fURS is associated with a lower likelihood of repeat procedure; therefore, the patient will become stone-free quicker than with ESWL [9, 10, 66]. No meta-analysis for renal stones has been published yet due to the lack of randomized control trials, except for lower pole renal stones.

### Large renal stones (>20 mm)

Although PCNL remains the first-line treatment for renal stones >20 mm, fURS as an option has emerged in some studies, pushing the limits of this technique. Recent publications have reported successful treatment of large stones using single or staged ureteroscopic procedures [67–69]. A meta-analysis published in 2015 found that PCNL provides a significantly higher stone-free rate (odds ratio [OR], 2.19; 95% confidence interval [CI], 1.53–3.13; $P < 0.001$) and higher complication rates (OR, 1.61; 95% CI, 1.11–2.35; $P < 0.001$) compared to single-session fURS for stone burden >10 mm [69]. Another meta-analysis assessing the outcomes of fURS for stones >20 mm found a mean of 1.46 ± 0.2 procedures per patient with 20–30 mm renal stones compared with 1.85 ± 0.02 for those with renal stones >30 mm. Stone-free rates after treatment completion were 95.7 and 84.6%, respectively [69]. Large stone burden can be treated by fURS but the patient has to be informed that a staged procedure may be required.

### Lower pole renal stones

A recent meta-analysis comparing ESWL, fURS, and PCNL for the treatment of lower pole renal stones reported a stone-free rate of 89.5% versus 70.5% for fURS and ESWL, respectively. Subgroup analyses revealed that fURS was more effective than ESWL for 10–20 mm stones (85.5 vs. 57%) but this benefit was markedly less for ≤10 mm stones (90% for fURS vs. 79.9% for ESWL) [70]. A preleminary study reported no significant difference in stone-free rates between PCNL and fURS for 11–25 mm lower pole renal stones (45.6% for fURS vs. 66.7% for PCNL) [70].

## Complications

A recent study including 11 885 patients who underwent an ureteroscopic procedure found an overall complication rate of 7.4%. The intraoperative and postoperative complication rates were 4.2 and 2.6%, respectively, and a total of five deaths were reported between January 2010 and October 2012. However, these rates do not distinguish the complications associated with fURS or semirigid URS. The location of the stones was ureteric and renal in 73 and 15.6%, respectively [71]. (See also Chapter 56.)

## Conclusions

fURS has become widely used due to the technical advancements and refinements made in the endourologic armamentarium over the last three decades. The high efficacy and low morbidity in the treatment of renal stones up to 20 mm have made it a treatment of choice for the management of renal calculi.

# Diagnostic Ureteroscopy

*Hendrik Heers*[1] *& Benjamin W. Turney*[2]

[1] *Department of Urology, Nuffield Department of Surgical Sciences, University of Oxford, Oxford, UK*
[2] *University of Oxford and Oxford University Hospitals NHS Foundation Trust, Oxford, UK*

## Indications

From the advent of ureteroscopy (URS) the procedure has been used for diagnostic purposes [1–3]. As the early instruments lacked a working channel, diagnosis was actually its initial primary function. The equipment has experienced significant innovation ever since, broadening indications and refining results. Diagnostic URS is still not perfect and should only be seen as one step in a suite of investigations along with ultrasound, computed tomography (CT), or magnetic resonance imaging (MRI), and urine-based diagnostics, when looking at the upper urinary tract.

The main purpose of diagnostic URS has always been the detection of upper urinary tract urothelial cancer (UTUC). Established indications are hence derived from surrogate markers of this disease. Every patient presenting with visible hematuria or persistent nonvisible hematuria warrants a urological workup. Besides urine dipstick and culture, cystoscopy is performed to evaluate the lower urinary tract. The upper tract is usually primarily assessed with radiological techniques: ultrasound, CT kidney–ureter–bladder (KUB), and CT urogram, and – in select cases – intravenous pyelogram (IVP). Stones as a source of hematuria can be reliably identified this way. If any of these investigations shows abnormalities suspicious of a tumor, diagnostic URS is recommended prior to any treatment. However, as all these investigations have limited sensitivity, a diagnostic URS should still be considered in the absence of radiological abnormalities if there is a strong clinical suspicion of UTUC (e.g. persistent hematuria in a patient with a history of bladder tumors or positive urine cytology with normal cystoscopy) or in situations where early diagnostic accuracy is paramount (e.g. solitary kidney).

Classical findings suggestive of UTUC are hydronephrosis in the absence of ureteric calculi (differential diagnoses: ureteric stricture, pelviureteric junction [PUJ] obstruction, compression of the ureter) on CT KUB and contrast-filling defects on CT or IVP. Only tumors of a certain size are directly visualized on CT or ultrasound at which stage they are often invasive. This is the case for 60% of UTUC at primary diagnosis [4].

Other indications for diagnostic URS are follow-up after organ-sparing treatment of UTUC and in individual cases after radical cystectomy for transitional cell carcinoma (TCC) of the bladder, for example if a cutaneous ureterostomy has been established.

The procedure may also be used to investigate ureteric strictures, cases of suspected ureteric endometriosis, and other rare changes of the upper urinary tract (e.g. amyloidosis).

## Patient preparation

The preparation for diagnostic ureteroscopy should be even more vigorous than for other endourological procedures due to its delicate nature and susceptibility to confounding factors. All patients must have their urine cultured prior to the intervention and any urinary tract infection should be treated with antibiotics. Indwelling ureteric stents should be removed at least 3 weeks ahead if possible as they can provoke inflammatory changes rendering an endoscopic diagnosis of smaller lesions impossible.

The consenting process should include injuries to the lower urinary tract and ureter requiring open surgical repair, formation of strictures, hydronephrosis, and the necessity to insert a ureteric stent. Any intended simultaneous therapeutic procedure must also be addressed.

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.
© 2019 John Wiley & Sons Ltd. Published 2019 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/smith/textbookofendourology

All patients with suspected UTUC should be assessed with CT urogram (or MRI urogram in cases of impaired kidney function or allergy to iodine-containing contrast agents) prior to endoscopy in keeping with the European guidelines, whereas the American National Comprehensive Cancer Network guidelines do not make specific recommendations on the sequence [4, 5]. If a tumor is detected, a diagnostic URS should be performed prior to nephroureterectomy. Not only should a histological diagnosis be obtained but there is also a cohort of patients with small low-grade lesions who might benefit from organ-sparing treatment. Up to 42% of patients would receive unnecessary over treatment without diagnostic URS [6].

Diagnostic URS should not be considered for atrophic kidneys as this is an indication for nephrectomy. If the radiological findings are suggestive of a nonfunctioning kidney, a MAG3 or $^{99m}$Tc-labeled dimercaptosuccinic acid (DMSA) renogram should be considered for confirmation.

Single-shot antibiotic prophylaxis for diagnostic URS is currently a point of discussion. In the absence of risk factors, it can be omitted as the incidence of sepsis is very low [7].

## Instruments

It is important to use as little equipment as possible in order to visualize the ureter and collecting system in its original state, avoiding artificial injuries interfering with the inspection. Semirigid and flexible ureteroscopes are available, typically with a diameter between 6 and 10 Fr. They have either one or two working channels.

Due to the high maintenance costs and frequent need for repair of flexible ureteroscopes, disposable instruments have been introduced to the market recently. Furthermore, although fibre-optics have traditionally been used for flexible ureteroscopy, the advancements in digital optics ("chip on the tip") offer better image quality. Their use has systematically been validated in URS for stone removal. While stone-free rates and complications are comparable to fibre-optic scopes, the duration of procedures has significantly been reduced [8, 9]. Despite a lack of literature, it may be expected that the diagnostic accuracy of the new digital instruments is superior thanks to their enhanced image quality.

A plethora of auxiliary equipment is available for ureteroscopy: guidewires of variable stiffness both hydrophilic and nonhydrophilic, ureteric catheters, balloon dilatation catheters and other devices to facilitate entrance into and passage through the ureter, as well as therapeutic devices which may be applied during diagnostic URS, including baskets, biopsy forceps, and laser fibres. Balloon dilatation catheters bear a significant risk of injury to the ureter and can even result in tumor spillage if a perforation arises, so their application needs to be considered very carefully in diagnostic URS. If no access to the ureter can be obtained, it might be the better option to insert a ureteric stent and bring back the patient for a second look after 1 or 2 weeks.

## Technique

Every diagnostic URS begins with a close inspection of the urethra and bladder to rule out concomitant lower urinary tract lesions such as bladder tumors or prominent vessels in the prostatic urethra. Subsequently, the ureteric orifices (UOs) are identified and closely monitored for uni- or bilateral hematuric urine ejaculation. After exclusion of tumors, bilateral upper tract hematuria is suggestive of a glomerular cause which should be evaluated by a nephrologist.

If the UOs cannot be identified due to inflammatory changes to the mucosa, bleeding, or a large prostate, a rigid cystoscope with an angulated optic should be used. It might be sufficient to fill up the bladder in order to bring the UOs into view. The use of intravenous methylene blue should be omitted as it will impair the diagnostic quality upon entry into the ureter.

A semirigid ureteroscope should be used for inspection of the ureter to the PUJ. An experienced surgeon is often able to intubate the UO without using a guidewire. This has the advantage of omitting mucosal lacerations by the wire but bears an increased risk of injury to the ureteric wall. The risks and benefits in the individual situation must be outweighed against each other. The authors advocate using a hydrophilic guidewire routinely.

Due to the shape of the ureteroscope's tip it is advisable to twist the instrument by 180° (clockwise for a right-handed surgeon) to obtain an atraumatic intubation with fully opened irrigation. In this position, by lowering the tip, the UO can be widened slightly. Once the tip of the scope is passed into the distal ureter, it is twisted back into its original orientation.

If the UO is too tight to allow direct entrance, a hydrophilic guidewire should be used in the same technique. In case this is not sufficient, a ureteric catheter can be used instead as it has the advantage of higher rigidity. Any dilating devices such as balloon catheters or access sheaths can potentially injure the ureter and should be avoided wherever possible during diagnostic URS. If any of these devices is used, a guidewire should always be placed into the mid ureter. Hydrophilic guidewires are preferential as they are less traumatic. A guidewire with a hydrophilic tip and a more rigid body is a good compromise between preserving the mucosa and assisting with the passage of the instrument. Fluoroscopy for orientation is highly recommended. Any forced movements must strictly be avoided as they can result in a discontinuing injury of the ureter already in its intramural portion.

If a bladder tumor occludes the UO or if there is a stenosis following a transurethral resection, it may be necessary to perform another resection first before obtaining access to the ureter. This maneuver has a risk of ongoing vesicoureteric reflux and perforation. In almost all cases however, the UO can be intubated without problems, even with a flexible ureteroscope [10, 11].

With the scope in the distal ureter, a retrograde ureteropyelogram should be performed. Air bubbles in the syringe must be avoided. Any filling defects are noted. The images help during the navigation, especially inside the kidney. It is important to inject the adequate amount of contrast agent, allowing complete visualization of the ureter and collecting system but avoiding extravasation and bleeding of small vessels.

To improve the diagnostic quality when looking for UTUC, several urine cytologies should be taken, usually from the bladder, on three levels of the ureter, and subsequently in all portions of the kidney as well as targeted on any suspicious lesions. Cytology has limited sensitivity, particularly for low-grade tumors, but high specificity.

When advancing the ureteroscope, the ureteric lumen must remain central in the field of view so that the entire circumference of the wall can be inspected. Any obstacles such as kinks can usually be passed with the help of a (hydrophilic) wire or if necessary a ureteric catheter. Major kinks in a chronically ectatic ureter can sometimes be resolved by positioning the patient head down for a short while. Increasing the irrigation pressure can also be helpful but should be used sparingly to avoid overdistension with subsequent urothelial bleeding.

Extrinsic filling defects can often be determined visually with the appearance of compression of the ureter in the absence of any intrinsic mass in the ureteral lumen. When the ureter is extrinsically compressed by a venous structure, the ureteral lumen is distensible during ureteroscopic inspection, whereas extrinsic compression from an artery often results in visible pulsations. Ureteral strictures and PUJ obstructions also may be visually confirmed.

The semirigid ureteroscope can be used until gaining entrance to the renal pelvis. The instrument of choice for inspection of the proximal ureter and the collecting system is the flexible ureteroscope. Thus, a hydrophilic guidewire is placed through the semirigid instrument into the renal pelvis under vision. The ureter can usually be inspected more effectively when slowly drawing back the scope, rather than during the advancement. After removing the semirigid scope, a flexible instrument is inserted via the guidewire which can subsequently be removed. Using the previously performed retrograde pyelogram for guidance, the entire collecting system is carefully inspected. Again, urine cytologies should be obtained from several sites in the kidney.

Towards the end of the procedure, the flexible ureteroscope is removed, allowing for a final inspection of the ureter. After an uneventful diagnostic URS, a ureteric stent is usually not required. If there is a risk of obstruction or significant bleeding, a stent may be inserted.

## Diagnosis of upper tract urothelial cancer

Some 5% of TCCs are localized in the upper tract, more commonly in the ureter than in the collecting system, in keeping with the relative amount of urothelial surface. Tumors in the upper tract have an appearance similar to bladder tumors: they are mostly exophytic and papillary but there can also be flat reddish lesions, especially when carcinoma *in situ* is present. These are easily missed on inspection, especially with older instruments and optics. Many patients with TCC have multifocal disease. After nephroureterectomy, further lesions are reported after histology that were not detected on URS in 25% of patients [12]. Figures 49.1 and 49.2 show examples of TCC in the renal pelvis.

Fibroepithelial polyps, while often long and papillary, can be distinguished from upper urinary tract TCC as they frequently have a smooth, normal-appearing urothelial surface whereas TCC often show hypervascularization and in later stages can be necrotic.

The location of any tumor should be documented as exactly as possible to optimize further treatment planning. Every suspicious lesion should be biopsied. As every diagnostic component for UTUC has its own flaws, only the combination of imaging, endoscopic inspection, cytology, and biopsy is adequate. The presence of hydronephrosis, positive cytology, and high-grade tumor on biopsy correlate with ≥ pT3 disease [13].

Biopsies can be obtained with forceps or stone baskets. Forceps are useful for flat lesions whereas baskets can be helpful for exophytic tumors which can be completely removed if the basket is placed around the stem. If forceps are used, multiple biopsies should be taken as the volume with each biopsy is very small. The histological sample should include muscular tissue but, at the same time, a perforation should be avoided as it can lead to tumor spillage. If reasonable, a basket should be used as it harvests better results in terms of successfully obtaining a representative tissue sample and correctly grading a tumor [14]. Video 49.1 shows an example of a basket biopsy of TCC recurrence in the renal pelvis of a patient with ileal conduit.

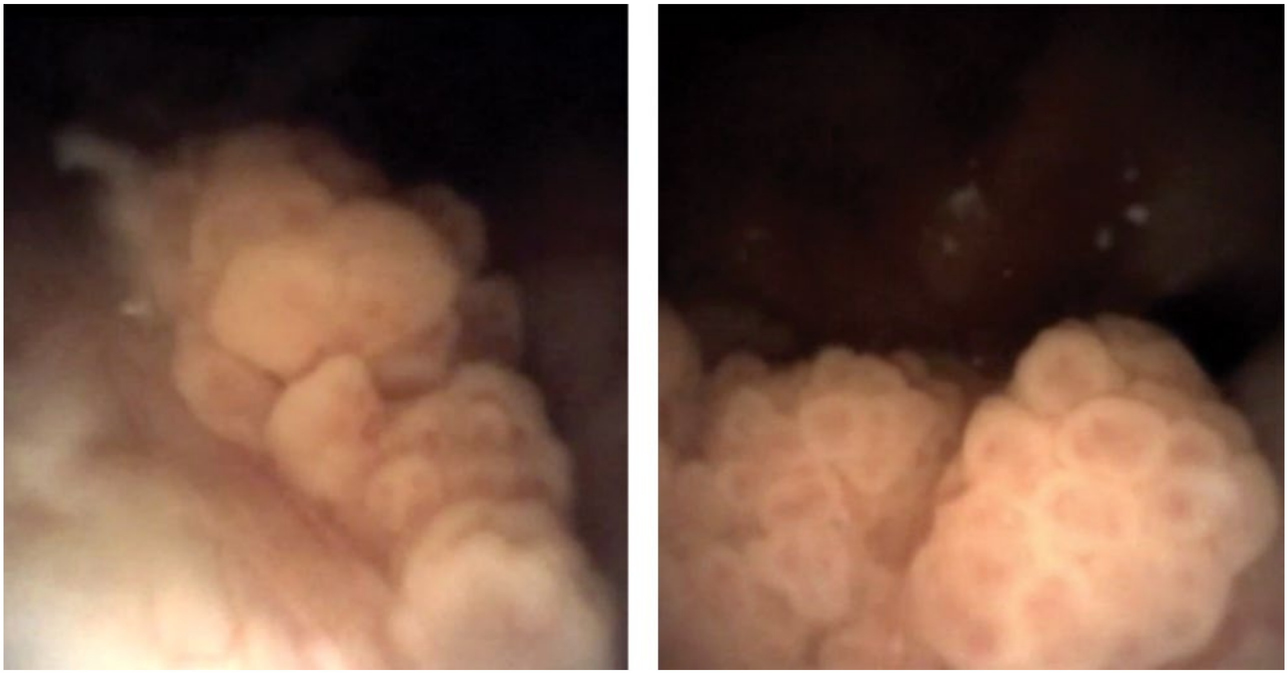

**Figure 49.1** Ureteroscopic impression of exophytic TCC in the renal pelvis. Images courtesy of Mr Oliver Wiseman, Cambridge, UK.

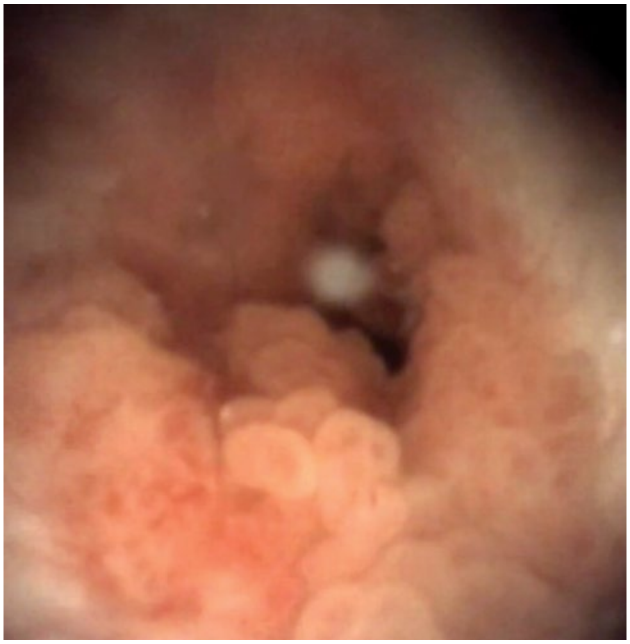

**Figure 49.2** Further tumor material in the same patient. Image courtesy of Mr Oliver Wiseman, Cambridge, UK.

While tumor grading with biopsies is 79–93% accurate, assessing the local stage is problematic [15–18]. Many tumors are upstaged following nephroureterectomy. High-grade tumors on biopsy are suggestive of invasive stages (≥pT2), which are found in around 60% of cases.

## Endoscopic treatment of upper tract urinary cancer

Upper tract TCC can be treated endoscopically with either diathermy resection using a special ureteric resectoscope or preferably a holmium laser. Nephroureterectomy remains the gold-standard therapy but in select patients an organ-preserving treatment regimen may be selected. This is the case in patients with low-grade and low-stage disease, a solitary kidney, severely impaired kidney function, bilateral tumors in the upper tract, and patients unfit for major surgery.

For tumors of the renal collecting system, a percutaneous approach is feasible, however this bears the risk of tumor cell spillage. Thus, ureteroscopic treatment is often preferred.

If nephroureterectomy is indicated, ureteroscopic management should only be offered to patients with small, low-grade tumors. The patient must be informed about the potential undergrading and understaging through biopsy (see above) and that a purely endoscopic treatment requires a rigid follow-up with semi-annual ureteroscopies as there are higher recurrence rates than with radical surgery. Adjuvant treatment with mitomycin and BCG has been described but is not the standard of care.

For an adequately selected patient group, the rate of secondary nephroureterectomy has been reported to be around 20% [19].

The use of a holmium:YAG laser for tumor ablation is the option of choice as its penetration into tissue is only 0.4 mm, thus the risk for perforation is comparatively low. Papillary tumors can be removed and subsequently the surface is coagulated for hemostasis. Neodymium:YAG lasers may also be used for larger tumors. They penetrate deeper (2–5 mm) and have a larger extent of thermic tissue destruction.

## Other causes for hematuria

If tumors and stones are ruled out, other causes for hematuria have to be considered. Bilateral ureteric hematuria is usually a glomerular problem. Other benign causes of hematuria are hemangioma and arteriovenous malformations. The term “nutcracker syndrome” describes a compression of the renal vein by other structures resulting in a rising intravenous pressure that subsequently leads to glomerular hematuria. Angiography with measurement of the intravasal pressure may be necessary for its diagnosis.

## New technologies and perspectives

Due to the limitations of diagnostic ureteroscopy that have already been described in this chapter there is an increasing number of auxiliary technologies on trial to enhance the diagnostic value.

- *Photodynamic diagnosis (PDD)* has been established for the diagnosis of bladder TCC for years. Hexaaminolaevulinic acid (5-ALA) is instillated into the bladder prior to endoscopy. It intercalates with replicating DNA and thus accumulates in malignant (and inflammatory) tissue. Light waves with a length of 400 nm excite the electrovibrational state of the fluorochrome. Upon relaxation to the ground state, a photon is emitted (wavelength 590–700 nm), permitting optical diagnosis of tumors. For the purpose of upper tract diagnostics, 5-ALA can be administered through a ureteric catheter or orally. Episodes of hypotension have been described as a side effect. Some authors describe enhanced sensitivity but the technique has limitations. PDD works best with a perpendicular view onto the tissue. On tangential visualization as in ureteroscopy, it can lead to false-positive results [20, 21].
- *Optical coherence tomography (OCT)* has first been employed in ophthalmology. It employs a similar principle to ultrasound but uses light waves and covers a depth of up to 2 mm. The measurement of the attenuation coefficient $\mu_{\mathrm{OCT}}$ allows for differentiation of tissues. Only few data on its use in diagnostic URS is available yet [22].
- *Confocal laser endomicroscopy (CLE)* is another technique using fluorescence, in this case by injecting fluorescein intravenously. It allows ultra-high-resolution imaging of tissue microarchitecture but only has a depth of up to 400 μm. A drawback is the susceptibility to motion artefacts. Further studies are needed to prove an enhanced diagnostic value [20, 23].
- *Narrow-band imaging (NBI)* relies on the absorption of light at specific wavelengths by hemoglobin; hence microvessels are better visualized. Apparently, this improves sensitivity up to 23%, but again, further studies are required [20, 24].
- *SPIES® (Storz professional image enhancement system)* uses spectral separation by digital filters in order to enhance contrast. There is no literature on its application in the upper tract available yet [20].

In conclusion, diagnostic URS is an important step in the workup for UTUC and other pathologies of the upper urinary tract. The current technological advancements in optics, endoluminal imaging, and image processing offer promising enhancements to further the sensitivity and specificity of upper urinary tract endoscopy.

# Ureteroscopic Diagnosis and Treatment of Upper Urinary Tract Neoplasms

*Scott G. Hubosky & Demetrius H. Bagley*

*Department of Urology, Sidney Kimmel Medical College at Thomas Jefferson University Hospital, Philadelphia, PA, USA*

Ureteroscopy is an essential technique in the diagnosis, treatment, and surveillance of upper tract neoplasms. The introduction of fiber-optic illumination, imaging, and small rigid and flexible ureteroscopes in the early 1980s provided access to the entire upper collecting system. This combination with devices for tissue sampling and ablation has made accurate diagnosis and treatment possible. Other diagnostic studies including radiologic, cytologic, and molecular techniques can provide initial or supportive diagnostic information, yet remain secondary to endoscopy as the definitive study.

Upper tract neoplasms are rare and upper tract urothelial carcinoma (UTUC) accounts for 5% of all urothelial carcinomas [1]. UTUC is more common in patients with a previous history of carcinoma of the bladder [2, 3]. The most common presentation is hematuria, either gross or microscopic, in approximately 80% of patients [1, 4, 5]. UTUC is an incidental finding in 10–15% of patients but flank pain can be seen in up to 30% of patients. Physical findings are rare, unless the patient has metastatic tumor or hydronephrosis secondary to obstruction.

Radical nephroureterectomy (RNU) with removal of a bladder cuff has been considered the standard for treatment of UTUC [6]. The application of endoscopic techniques to these lesions initially in patients with a solitary kidney or compromised contralateral kidney, which have been considered imperative indications, have shown the feasibility of this treatment. Consequently, it has been performed increasingly in patients with a normal contralateral kidney [7, 8]. Evidence of progressive functional renal loss in patients undergoing nephrectomy for renal cell carcinoma can also be expected in patients losing their kidney to nephroureterectomy and is a stimulus for nephron-sparing surgery [9].

## Noninvasive diagnosis

Radiologic studies, including intravenous contrast studies to outline the collecting system with excretory urography or computed tomography (CT) urography are the most useful noninvasive diagnostic techniques. A filling defect is the most common finding, which may indicate an upper tract urothelial neoplasm. The differential diagnosis includes blood clot, lucent calculus, air bubble, fungus ball, sloughed papilla, external compression with a crossing vessel, or benign inflammatory or neoplastic lesion. One series using a multidetector CT scanner for CT urography in patients with gross hematuria demonstrated a very high sensitivity, specificity, and accuracy [10]. In some patients with a severe contrast allergy with nonvisualization of the collecting system, retrograde ureteropyelography may be indicated. However, this suffers from low accuracy [4, 11].

Renal ultrasound can define intrarenal calculi, hydronephrosis, and renal masses accurately but is less useful to define small intraluminal soft tissue masses. In contrast, CT can accurately distinguish calculi from soft tissue masses. It is also helpful in demonstrating masses extending beyond the collecting system or enlarged lymph nodes. Inclusion of a pyelographic phase with reconstruction of the excretory system or an abdominal radiograph taken after the administration of contrast as an anteroposterior ureteropyelogram may be most useful in demonstrating intraluminal lesions [10, 12]. Magnetic resonance imaging has similar limitations, especially in the cross-sectional mode [13]. The magnetic resonance urogram designed to image the fluid of a distended collecting system may be helpful in some patients with nonfunctioning kidneys or severe contrast allergies.

Cytologic study of voided urinary samples is of limited value because of the frequent equivocal and false negative

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

findings. It can be useful in detecting high-grade tumors, which shed obviously malignant cells in the urine. The sensitivity of voided urinary cytology increases with an increasing grade, ranging from 11% for Grade 1 to 83% for Grade 4 lesions [14]. Elective ureteral catheterization for a specific and localized upper tract urinary sample for cytologic study is occasionally indicated in patients with positive cytology without radiographic findings and with normal cystoscopy and bladder biopsy. However, routine ureteral catheterization to collect urine from a radiographically abnormal area is no longer indicated if ureteroscopy can be performed. Similarly, fluoroscopic guided brush biopsy is rarely indicated when ureteroscopy is available.

Fluorescence *in situ* hybridization (FISH) has been used to detect genetic aberrations in chromosomes 3, 7, 9, and 17 and improves the sensitivity of voided urine cytology for all bladder lesions, including low grade, from 25 to 53% [15, 16]. The appeal of FISH would be to utilize it in voided urine specimens to detect UTUC without the invasiveness of ureteroscopy. The largest published reports of FISH in UTUC detection using voided urine specimens demonstrate increased sensitivity compared to voided cytology but it is still not sensitive enough to forgo ureteroscopic visualization for diagnosis [17–19].

## Endoscopic diagnostic techniques

Endoscopic evaluation of an abnormality in the upper urinary tract suspicious for a neoplasm includes inspection of the entire bladder and involved collecting system. Cystoscopy is an essential evaluation of the patient with hematuria and/or filling defects because of the risk of associated bladder tumors and to provide access to the ureter for retrograde pyelography and ureteroscopy. A retrograde ureteropyelogram may give more information regarding the extent of the filling defect or suspicious lesion or ureteral abnormalities, which might affect access for treatment. A cone-tipped retrograde injection most efficiently outlines the entire collecting system without traumatizing the ureter itself. Care should be taken to prevent overfilling of the collecting system, which can obscure filling defects. Initial ureteral catheterization without contrast study should be avoided since it can traumatize the specific lesion of interest and the otherwise normal ureteral mucosa.

A "no-touch technique" should be employed to examine the involved upper collecting system. The distal ureter is first inspected either with a small rigid endoscope, preferably one small enough to pass into the orifice without other dilation, or with a flexible ureteroscope that can be passed into the ureter without dilation [20]. In this way, the ureter can be inspected without prior instrument trauma. When using a semirigid ureteroscope, it is passed as far as possible into the lumen before leaving a guidewire in place as the endoscope is removed. The guidewire is passed only to the level of the ureter that has been inspected with the semirigid ureteroscope and should not be passed into the intrarenal collecting system where the tip of the wire can traumatize the calyx or the renal pelvis and obscure subsequent visual inspection. The smallest flexible ureteroscope is then passed over the guidewire into the ureter. If a small flexible ureteroscope can be passed directly into the ureter, then the steps of semirigid ureteroscopy and wire placement can be avoided.

The flexible ureteroscope is used to inspect the more proximal portions of the ureter not previously seen and the intrarenal collecting system. Inspection at that level should be systematic going from the renal pelvis to the upper infundibula and calyces to the mid and then the lower pole. In this way, the risk of trauma to the mucosa with the endoscope is minimized.

Continuous irrigation with saline is maintained through the working channel of the ureteroscope to clear the field of view. Iodinated contrast medium can be used in the irrigant to outline the collecting system for fluoroscopic monitoring. Positioning of the flexible ureteroscope throughout the collecting system can then be confirmed fluoroscopically. Care must be taken to avoid overfilling the collecting system, since this can induce submucosal hemorrhage and rupture of the fornices. When adding contrast through the endoscope within the collecting system, the irrigant present should be removed. Lines of refraction will be visible as fluids of two different densities mix. This can be avoided by minimizing the mixing.

If there is a specific lesion to be examined, such as a filling defect or a point of obstruction, then the distal portion of the urinary tract should be inspected first, followed by the lesion itself in order to inspect it within a clear visual field without other manipulation that may cause bleeding and obscure the field of view. In many cases, visual inspection alone can provide a diagnosis [21–24]. For example, the appearance of a calculus will readily distinguish it from a low-grade papillary tumor. Irrigant with contrast should be used so that fluoroscopy can demonstrate the tip of the ureteroscope at the filling defect. In this way, correct visualization and identification of the lesion can be confirmed.

Epithelial neoplasms may have totally different appearances. Low-grade UTUC has a typical papillary appearance, similar to the same lesions in the bladder (see Videos 50.1, 50.2a,c, and 50.3). High-grade UTUC may be more sessile and less papillary, often with necrotic or inflammatory debris on the surface. However, these differences are not consistent. El-Hakim and colleagues [25] found an accuracy of only 70% in determining the grade of an upper tract neoplasm by appearance alone.

Benign lesions can often be diagnosed endoscopically. Fibroepithelial polyps located within the pelvis and inverted papillomas throughout the upper collecting system have been seen to have a smooth, rounded surface [26]. There may be an impression of an intact epithelial layer in the appearance. These differences have not been prominent enough to allow visual identification, but they have been strongly suggestive. All benign lesions observed, including fibroepithelial polyps, inverted papillomas, and hemangiomas located in the ureter or the ureteropelvic junction can be narrow, elongated, and worm-like.

In many instances, visual inspection alone may not be adequate for diagnosis. High-grade UTUC can be confused with inflammatory lesions or may be obscured by tumor growing submucosally or proximal to obstructive edema. There may be calculus material on the surface of a neoplasm with the resultant appearance of a solid calculus. Other tumors with a necrotic surface can appear the same as a soft, infection stone covered with inflammatory debris. In these and many other situations, visual inspection alone is not adequate for diagnosis.

Aids to visual diagnosis of neoplasms such as narrow-band imaging (NBI) and confocal laser endomicroscopy have been used in the bladder to detect carcinoma *in situ* or additional exophytic tumors. NBI is an optical image-enhancement system that makes use of blue and green wavelengths of light, which are readily absorbed by hemoglobin to enhance surface tumor detection by providing contrast between normal mucosa and microvasculature. Since malignant lesions tend to have a rich vascular component, they appear dark brown or green against white mucosa thus enhancing lesion detection. One report of NBI for use in cases of UTUC found a 23% improved detection rate among 27 patients in which additional tumors were seen or borders of tumors were enhanced and noted to extend beyond what was observed with white light alone [27]. NBI also has value in differentiating benign inflammation, as seen from indwelling stents, from subtle malignant luminal lesions [28]. Unlike photodynamic diagnosis modalities, NBI requires no extrinsic fluorochrome, an attractive aspect for use in the upper tracts.

## Endoscopic biopsy technique

Ureteroscopic biopsy is necessary to sample neoplasms in the upper urinary tract to determine the presence of malignancy, and to determine the grade. The rate-limiting step of ureteroscopic biopsy is the size of the working channel within the ureteroscope, which dictates the size of the biopsy instrument that can be used. For example, a piece of tissue obtained with a 3 Fr cup biopsy forceps is less than 1 mm in diameter and is usually too small to be prepared for histologic study using standard techniques. It is often lost in the process (see Video 50.1a). In contrast, it is a relatively large fragment of tissue for cytologic techniques. It can be prepared as a cell block and stained and examined as a histologic preparation to give a diagnosis and possibly grade.

Several different biopsy instruments and techniques are available. Abdel-Razzak and colleagues [29] evaluated samples from 55 procedures in 44 patients with a possible diagnosis of UTUC. They compared the diagnostic yield, considering only those samples that were specifically positive or negative for malignancy, excluding those that were “suggestive” or equivocal. The techniques compared aspiration of urine at the level of the lesion, wash and aspiration with saline solution at the area of the lesion, and direct tissue sampling with brush, basket, or biopsy forceps.

The tissue sampling techniques gave the best yield, particularly the flat wire basket for large friable tumors and the cup forceps for more sessile lesions. The brush was less effective, and under endoscopic vision was observed to move the more flexible tissue without removing fragments. It may be more useful with flat or sessile lesions. Aspiration and wash proved to be valuable in providing a diagnosis for some patients in whom the other sampling techniques were inconclusive.

A flat wire basket is quite effective for removing large fragments of papillary tissue with a small-diameter ureteroscope (see Videos 50.2a–c and 50.6). We highly recommend this instrument for biopsy of UTUC whenever applicable since it has been shown to be superior to the 3 Fr cup biopsy forceps in securing a diagnosis of UTUC in suspected lesions [30]. Under endoscopic vision, the basket is placed on the tumor and partially closed. The entire unit consisting of tumor sample, basket, and ureteroscope is then removed from the ureter and bladder. This can often remove a large sample even up to 1 cm in diameter, which is adequate for cytologic or histologic study. The ureteroscope is then replaced to repeat the inspection and biopsy or treat the neoplastic lesion.

The most important steps in handling the tissue for pathologic diagnosis is to work closely with the cytopathologist [31–34]. Samples are examined with both a smear and cytospin preparation. If there is any macroscopically visible tissue in the sample, a cell block is also prepared. This sample often demonstrates both the architecture of the neoplasm and the individual cells to allow grading of UTUC in many of the samples adequate for cell block. Multiple samples of the lesion are taken.

**Box 50.1 Specimens for cytology.**

- Bladder urine
- Aspirate at tumor
- Biopsy
- Aspirate after biopsy
- Aspirate after treatment

In addition, urine and saline wash samples of the lesion before and after biopsy and/or treatment are also obtained (Box 50.1).

## Grading with ureteroscopy

Grading of UTUC is important in determining prognosis and directing therapy. Grade obtained from ureteroscopic biopsy has been shown to reflect the grade of the overall tumor with reasonable accuracy. In 42 patients, Keeley and colleagues [35] found that the grade seen on a ureteroscopic biopsy prior to surgical treatment matched that in the final pathologic specimen in 38/42 (90%) of cases. Daneshmand and colleagues [36] showed an overall accuracy of 90% in patients who had surgery early after biopsy and in those who had surgery within 2 months of ureteroscopic diagnosis. In a larger, more recent series, Brown et al. demonstrated ureteroscopic grading accuracy in 112/119 (94%) of patients [37]. Other groups, however, have expressed concern over grade discordance between ureteroscopic and surgical specimens such that 23/24 (96%) of grade 1 lesions and 23/57 (40%) of grade 2 lesions were upgraded [38]. This exceptional finding is likely explained by the use of multiple grading systems for urothelial carcinoma used over the years, which are not simply interchangeable. In the surgical pathology literature, grade 2 UTUC lesions as defined by the 1973 World Health Organization (WHO) classification have demonstrated significant heterogeneity such that up to 50% of them would qualify as high-grade lesions according to the 1998 WHO system [39, 40]. This is very important to consider whenever interpreting studies involving the ureteroscopic treatment of UTUC over time since most studies are retrospective single institutional experiences taking place over many years in which the grading systems had changed. To consider all 1998 “low-grade” UTUCs as 1973 grade 1 cases would certainly explain the high rate of grade 1 upgrading to grade 2 in the 2012 Mayo series. Nevertheless, the possibility of UTUC tumors being heterogeneic in regard to grade must be considered, especially in view of the findings with urothelial carcinoma of the bladder in which up to 29% of primarily low-grade non-muscle invasive tumors had a high-grade component of at least 5% tumor volume [41]. The heterogeneity of grade 2 lesions also explains the benefit of combining site-specific cytology with ureteroscopic biopsy in patients with grade 2 UTUC to provide a more accurate diagnosis [42].

## Staging

Pathological stage has been shown to be the best predictor of prognosis in patients undergoing treatment for UTUC [43, 44]. Many factors are responsible for unreliable UTUC staging with ureteroscopic biopsy techniques including small specimen size due to limits of instrument size, relative thinness of the ureteral wall which could lead to extravasation with aggressive biopsy and the variable morphologies of the intrarenal collecting system resulting in “hard-to-reach” lesions. It is impossible to expect reliably complete excisional biopsies in the upper tract. Contemporary series report stage concordance rates of only 49–68% with the overwhelming trend demonstrating understaging of ureteroscopic biopsies [42, 45, 46]. Reliably determining the depth of invasion of the primary tumor or other simultaneous lesions remains difficult. One series advocated multiple deep biopsies with cup forceps in an attempt to determine the presence of tumor in the lamina propria [47]. Most series have not reported accuracy in determining the depth of invasion.

The grade of the primary tumor has often been associated with stage, but it cannot be considered truly accurate staging. In Keeley’s series [35], increasing stage was noted with increasing grade seen on ureteroscopic biopsy. Brown and colleagues also found that the grade on endoscopic biopsy correlated with the final pathologic stage in nephroureterectomy specimens [37]. Findings from these two studies demonstrated that low-grade UTUC on ureteroscopic biopsy correlated with noninvasive stage ($\leq$pT1) in 73–86% and that high-grade UTUC on biopsy results in more invasive cases ($\geq$pT2) in 66%. Other series of patients treated surgically have also demonstrated the relationship of increasing stage with increasing grade [48].

Cross-sectional imaging is essential for determining the presence of overtly metastatic disease but historically has not been very accurate in predicting subtly invasive disease (pT2–pT3). Favaretto et al. recently presented a model which combines ureteroscopic biopsy results with cross-sectional imaging and predicts $\geq$ pT2 disease with an accuracy of 71% [49]. Endoluminal ultrasound has been used in two series in an attempt to determine the depth of invasion [50, 51]. It has shown some value but is severely limited by the availability of the instruments.

Optical coherence tomography (OCT) is a new technological advancement that makes use of backscattered light to produce micrometer-level resolution cross-sectional images such that layered tissue anatomy can be appreciated. A 2.7 Fr probe can be placed through the lumen of a flexible or semirigid ureteroscope at the level of a urothelial lesion for cross-sectional imaging. Depth of imaging is reported at 2 mm and OCT staging is binary such that invasive disease is classified as $\geq$ pT1. An early validation study compared OCT stage to surgical stage after RNU and demonstrated 100% concordance in seven cases using the binary classification [52]. One case could not be staged due to tumor thickness going beyond OCT imaging depth. More experience is needed before the utility of this modality is fully appreciated.

## Complications of biopsy

There remains some concern that ureteroscopic biopsy of UTUC can disseminate tumor cells locally or systemically. The possibility of pyelovenous or pyelolymphatic backflow has been cited as a possible mechanism. In a single case report, tumor cells were found outside the kidney in a nephroureterectomy specimen after ureteroscopic biopsy [53]. However, in a review of 13 nephroureterectomy specimens following ureteroscopic biopsy, no unusual metastatic pattern was seen [54]. In a well-controlled study of 96 patients, Hendin and colleagues [55] found no difference in long term or disease specific survival in patients with UTUC who had surgical treatment preceded either with or without ureteroscopic biopsy (Table 50.1). Hara and colleagues [56] reported the usefulness of ureteroscopic biopsy and added 50 patients to those who have had ureteroscopic biopsy without development of metastatic disease. These series have concluded that ureteroscopic biopsy can be a safe and very valuable procedure without any documented evidence of tumor dissemination.

**Table 50.1** Effect of ureteroscopic biopsy.

| | Biopsy | None |
|---|---|---|
| No. of patients | 48 | 48 |
| Metastases | 12.6% | 18.8% (NS) |
| Died with recurrence | 10.4% | 10.4% (NS) |

Data from Hendin et al. [55]. NS, not significant.

## Selection of patients for ureteroscopic biopsy

Ureteroscopic biopsy is of value in any patient with an upper tract filling defect in whom the diagnosis is in question, such as those with a filling defect and voided urinary cytology without a definitive (positive) diagnosis for malignant cells. The presence of individually malignant-appearing cells (positive cytology) indicates either carcinoma *in situ* or a high-grade neoplasm. Biopsy may be avoided in patients with cytology that is definitively positive for malignant cells and who have a large irregular upper tract filling defects, which can be considered classic for UTUC. Even these patients should have endoscopy to rule out associated bladder tumor.

## Natural history and prognosis after extirpative surgery

The rationale for conservative endoscopic therapy of UTUC was based initially on the success of other conservative treatment modalities and the natural history of this neoplasm. The behavior and prognosis of UTUC, in both the ureter and the intrarenal collecting system, has repeatedly been shown to be related to the grade and stage of the lesion. In many early, published series of extirpative surgery for UTUC, the vast majority of cancer-related deaths were in those with high-grade disease, in whom muscle invasion was also frequently present. Survival of 49 patients with Grade I UTUC of the ureter or renal pelvis collected at the Mayo Clinic over a 22 year period was identical to that of an age-matched control group [57]. In contrast, the survival with higher-grade UTUC correlated with tumor stage and grade and was consistently lower than a control group [58]. Lymph node-positive disease also was dependent on tumor grade. In a series by Charbit and colleagues [48], lymphadenectomy was negative in all patients with low-grade tumors in whom it was performed while 39% of those in patients with higher-grade tumors were positive.

### Endoscopic therapy

Endoscopic therapy in the upper tracts for UTUC treatment is a natural extension of the well-accepted techniques for treating lesions in the bladder, only with smaller instruments imparting some unique limitations. The neoplasm itself, including its diagnosis, grade, location, and size, must be considered in any decision for endoscopic treatment in an individual patient (Table 50.2). There are several ureteroscopic techniques for the treatment of

**Table 50.2** Selection of patients for ureteroscopic treatment.

| Tumor factor | For | Against |
|---|---|---|
| Size | Small | Large |
| Configuration | Papillary | Sessile |
| Number | Solitary | Multiple |
| Distribution | Single | Circumferential or extensive |
| Grade | Low | High |
| Cytology | Negative | Positive |

UTUC and they include mechanical removal, electrosurgical resection, fulguration, and laser therapy.

The techniques used for the ureteroscopic biopsy of tumors result in the removal of tissue volume. A flat wire basket can remove several millimeters of papillary tumor with each application (see Video 50.6). Although the cup biopsy forceps removes a small volume with each bite, repetitive sampling can remove a small tumor (see Video 50.1a). The base of the tumor can then be coagulated with one of the other instruments (see Video 50.1b). Electrosurgical techniques similar to those used in the bladder have been applied for small distal ureteral neoplasms using longer, small-diameter endoscopes. Over time, this tedious procedure has been superseded by other more efficient techniques.

Ureteroscopic electrocoagulation of UTUC is possible using 2 or 3 Fr probes which can be passed through the channels of small-diameter rigid or flexible ureteroscopes. Care should be maintained to avoid fulgurating large areas of the ureter, which can result in stricture formation. This electrocautery technique is also useful for lesions within the intrarenal collecting system often in the lower pole medially where laser fibers may limit deflection of the ureteroscope. The 2 Fr electrode is slightly more flexible and can fulgurate with lateral contact rather than directly forward approach needed for a laser (see Video 50.5b).

Laser techniques have been applied safely and efficiently for UTUC treatment. Small fibers of 200–400 μm core diameter can be passed through the flexible ureteroscope. The two most commonly utilized lasers presently available can effectively treat UTUC with coagulation, ablation and resection. The neodymium:YAG laser was first used for treatment of bladder tumors and for renal pelvic and ureteral neoplasms in open surgical procedures achieving long-term cures [59]. It was subsequently used ureteroscopically to ablate urothelial carcinoma of the ureter [60]. In a comparative series, Schmeller and Hofstetter [61] demonstrated the success of laser ablation of upper tract tumors with the development of fewer ureteral strictures than after electrocoagulation.

The neodymium:YAG laser can penetrate up to 5 mm into tissue after several seconds of exposure. This can be controlled by positioning the fiber onto the tumor without directly aiming it toward the wall of the ureter and by moving the fiber across the surface of the tissue to avoid prolonged exposure. Ureteral damage may be limited by aiming the fiber and the beam parallel to the surface of the ureter. Within the kidney, especially the renal pelvis, where there is a greater surface area and less risk of scarring and stricturing, the neoplasm can be coagulated safely with the neodymium:YAG laser [62] (see Video 50.3). The laser is activated at 20–30 W on continuous mode and moved over the surface to coagulate the tissue. The effect can be seen as the color of the tissue changes to white. The laser fiber will char if it is activated in contact with tissue. For a relatively large lesion obstructing the ureter or an infundibulum, it may be necessary to remove some of the coagulated tissue with a basket or grasper to determine whether viable tumor remains. Since the laser can penetrate to a depth of approximately 5 mm, it may not affect the entire depth of the tumor. There have been no reports of significant renal or vascular injury or damage to associated organs from forward scatter of the neodymium:YAG laser that has been used in the renal pelvis.

The holmium:YAG laser has been widely applied for urologic indications. It is a solid-state pulsed laser that can fragment calculi and can coagulate and ablate tissue. This laser produces light at a wavelength of 2100 nm carried along a low-water-content fiber. The laser energy is absorbed within less than 0.5 mm of tissue or fluid and has essentially no risk of forward scatter. The effect observed is the only tissue effect achieved. It is particularly useful for ureteral lesions since it can ablate and remove a visually occlusive neoplasm to open the lumen for access [63–65] (see Video 50.4).

In use, the laser fiber must be placed in contact with or very close to the tissue to be treated. The laser is then activated at energies from 0.5 to 1 J at a frequency of 6–10 or even 15 Hz. Irrigation is maintained to clear the visual field of tissue debris. It is often necessary to discontinue treatment to allow the field to clear, since considerable debris is formed during treatment. Bleeding occurs occasionally and can be controlled better at lower energies or by moving the fiber slightly away from the tissue to diffuse the laser beam and improve coagulation. There is also clinical evidence that using longer pulse duration such as 700 microseconds, rather than the 350 microseconds often used for lithotripsy, will also improve coagulation (see Video 50.5a). The very limited penetration allows precise control and the laser, thus, can be used for ureteral lesions located at the level of the iliac vessels and the renal pelvis near the renal vessels. Great care is employed to avoid ablation and resection through the wall of the ureter or renal pelvis itself.

These lasers are best used in synergistic combination. The effects of the neodymium:YAG and holmium:YAG lasers are complimentary. The neodymium:YAG laser can be used to coagulate the major volume of tumor since it penetrates several millimeters and can achieve coagulation effect within the depth of the tissue. The coagulated tissue can then be removed mechanically or even more effectively with the holmium:YAG laser. The holmium:YAG is used to resect the tissue to the level of the wall of the ureter or renal pelvis. Thus, the benefits of each device can be used to the best advantage (Figure 50.1).

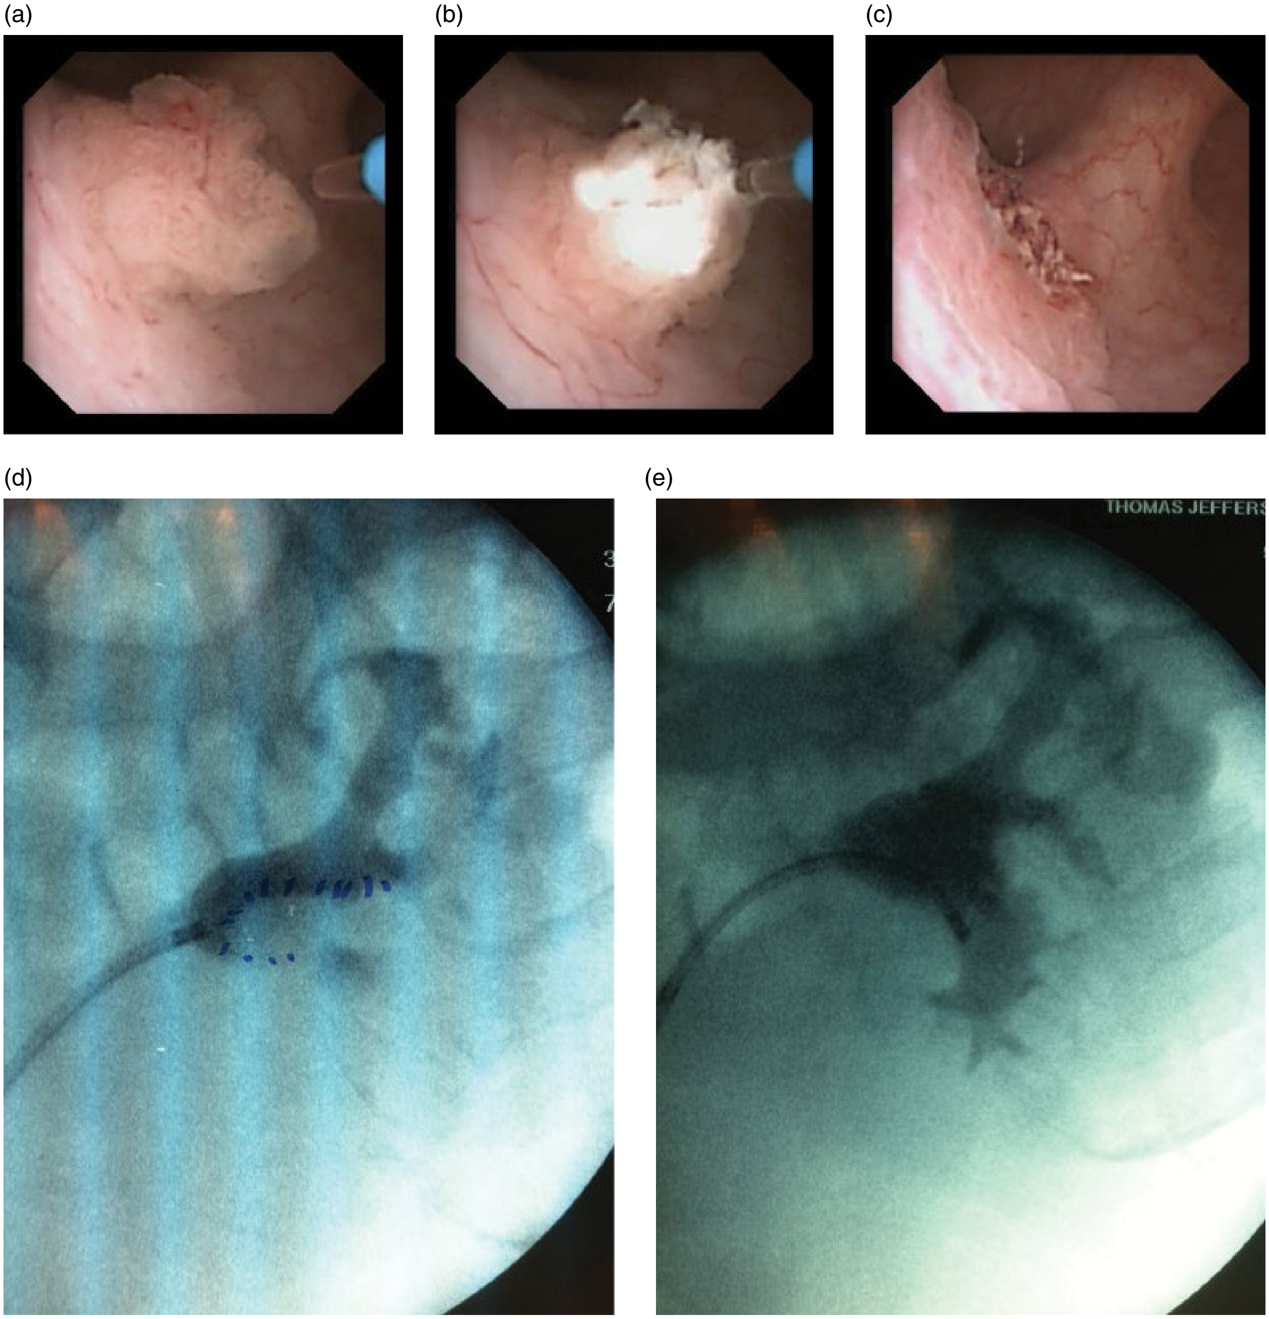

**Figure 50.1** (a) Digital flexible ureteroscopic image of a low-grade UTUC of the renal pelvis prior to laser resection. (b) Coagulation of the papillary tumor with the neodymium:YAG laser. (c) Complete ablation of the coagulated tumor which was resected with the holmium:YAG laser reveals the normal contour of the collecting system. (d) Fluoroscopic view of the left collecting system with contrast irrigation demonstrates a large papillary lesion in the renal pelvis with extension to a lower pole infundibulum. (e) Fluoroscopic view of the collecting system after ureteroscopic laser resection demonstrates the absence of masses and no evidence of extravasation. Moderately sized lesions can be effectively treated with the combination Nd and holmium:YAG laser which allows for less luminal bleeding and better visualization.

## Results of treatment

Ureteroscopic treatment of UTUC has been employed and studied for well over 30 years. There are many small retrospective series with variable tumor characteristics treated with non-uniform techniques and follow-up protocols. These are reported with various endpoints such as cancer-specific survival (CSS), local recurrence rates in the upper tract and bladder, renal preservation rate, and progression of disease defined in many different ways. Reports of metastatic disease are not uniformly presented, likely representing underreporting. Cohorts describing short- to intermediate-term results are plentiful while larger series with longer follow-up approaching 5 years have been published more recently. The indications for ureteroscopic treatment of UTUC have expanded from small low-grade lesions in patients with imperative indications to medium- and larger-sized lesions in patients with normal contralateral kidneys. Generally, recurrence rates become higher with longer follow-up, and treatment of larger, and high-grade, lesions. Non-malignant ureteral strictures are not uncommon as a result of repetitive manipulations over time.

## Recurrences

UTUC recurs at significant rates similar to locally treated bladder tumors. It is impossible to determine whether these new neoplasms are the result of implantation of cells from the original tumor or if it is related to a field change in the urothelium. Successful treatment depends on several factors A meta-analysis by Cutress et al. summarize the local recurrence rates and CSS of 20 contemporary ureteroscopic series in the treatment of UTUC [66]. Clearly, this is influenced by the grade of the original lesion with rates between 48 and 54% for low- to intermediate-grade lesions and as high as 60–76% for high-grade lesions. The grade of the original lesion also affects CSS with most series reporting rates of 86–100% with mean follow-up of 5 years or less (Table 50.3). Equally important are the length of follow-up and the size of lesions being treated. These factors vary widely from series to series but in general, local recurrence rates increase with longer follow-up and larger sized lesions. When considering the more recent series in Table 50.3, local recurrence rates of 77–90% are seen with series of more than 48 months follow-up [75, 77–79]. An exception to this trend was noted in the 2008 Mayo series with a 55% local recurrence rate with 59 month follow-up but the average lesion size treated in this series was only 8 mm [74]. In general, these recurrent lesions are small and can be treated endoscopically. A notable exception is when there is progression in grade from low- to a newly developed high-grade lesion. The rate of such grade progression has been defined by Grasso et al. as 15% at a mean of 38.5 months. This should be mentioned to patients considering ureteroscopic treatment for UTUC during initial consultation [78].

? Tumor location

Several characteristics of primary UTUC appear to be related to the risk of recurrence (Box 50.2), some of which are similar for those of bladder tumors. Recurrent disease is more likely for tumors over 1.5 cm in diameter than smaller lesions. There is also a higher risk of recurrence for high-grade tumors treated either ureteroscopically or by open surgery. There is evidence that positive urinary cytology at the time of treatment is a poor prognostic sign. The effect of the location of the primary tumor, whether in the intrarenal collecting system or ureter, has been inconsistent with some series reporting a higher rate for intrarenal neoplasms and others finding no difference or more frequent recurrence after ureteral primaries. However, multifocal lesions have consistently been seen to be associated with more frequent recurrences, both in the upper tract and in the bladder.

## Bladder tumors

There is significant risk of new bladder tumors developing in patients with upper tract neoplasms. The simultaneous initial presentation of urothelial carcinoma of the upper tract and bladder has been observed to be 17% in patients without prior history of bladder tumors [80]. The vast majority of bladder recurrences (80–90%) develops within the first 2–3 years of UTUC treatment [80] and tends to be nonmuscle-invasive in 88–95% of cases [81, 82].

In a recent meta-analysis including 8275 patients from 18 international centers undergoing RNU for UTUC between 2007 and 2014, Seisen et al. reported a pooled intravesical recurrence rate of 29% (range 21.5–46.9%) at median time 22.2 months with median follow-up of 43.8 months [83]. In contrast, Cutress et al. reported data on 22 ureteroscopically treated UTUC cohorts and noted a collective rate of intravesical tumor recurrence in 34% of patients with mean follow-up ranging between 14 and 73 months in another recent meta-analysis [66]. In two series specifically noting patients without previous bladder tumors, the rate was 34 and 33% [73, 76] (Table 50.4). In series with extended follow-up, the rate of bladder tumor occurrence is higher. Cutress et al. noted a 42% rate of bladder recurrences with mean follow-up of 52 months in 73 patients [79] while Grasso et al. noted 61% of 66 ureteroscopically treated patients developed bladder lesions with mean follow-up of 52 months [78].

**Table 50.4** New or recurrent bladder tumors: after ureteroscopic treatment of UTUC.

| Combined | 181/423 | 42.8 |

[a] No history of bladder tumor.
[b] Reviewed series to 2001.

It is difficult to compare patients treated ureteroscopically or surgically because of selection bias in treating patients. The endoscopically treated patients have lower-risk tumor characteristics but bladder tumor occurrence is similar in both groups. This fact highlights the need for diligent cystoscopic surveillance for UTUC patients regardless of primary treatment modality. Furthermore, this also raises the question for the need of postoperative intravesical chemotherapy in ureteroscopically treated UTUC patients even without the immediate simultaneous presence of a bladder tumor. As seen in the ODMIT trial with bladder tumor-naïve UTUC patients undergoing RNU, the rate of new bladder tumor development within the first postoperative year was lower in those receiving a one-time dose of intravesical mitomycin (16%) versus those who did not (27%) [84].

## Large tumors

Large neoplasms of the upper tract can be treated successfully ureteroscopically in some patients. It may be necessary to stage treatment at intervals of approximately 6 weeks. A combination of neodymium:YAG laser, coagulation, or electrocoagulation with holmium laser resection is effective. If visibility deteriorates with bleeding or tumor debris, it may be impossible to distinguish the margin of the tumor. The second resection may allow more precise treatment. Some tumors that regrow too rapidly or are too large to be treated ureteroscopically may require a percutaneous nephroscopic procedure or even nephroureterectomy.

## High-grade tumors

Numerous reports have correlated the presence of high-grade UTUC with invasive disease on extirpative surgical specimens [35, 37]. Therefore, the presence of high-grade UTUC precludes the employment of ureteroscopy as primary treatment with the intent to cure. Endoscopic treatment for high-grade UTUC is reserved for those patients medically unfit for extirpative surgery, those with renal insufficiency or those with solitary renal units unfit for conservative extirpative surgery who would otherwise need dialysis but are unwilling to commit to it. In these situations, ureteroscopic management should be considered palliative with the goal of stopping gross hematuria and limiting the need for hospitalizations. The same ureteroscopic techniques would be employed with focus on coagulation of bleeding tumors and ablation of obstructing tumors whenever possible. In certain cases, stent dependence is accepted in order to maximize drainage especially if malignant obstructing tumors are present and require extensive coagulation, which may lead to ureteral stricture formation. Patients undergoing ureteroscopic treatment for high-grade UTUC should be counseled on the very high probability of eventual development of metastatic disease, end-stage renal disease, or both. Although there have been rare reported cases of successful long-term ureteroscopic treatment of high-grade cases [71], the median overall survival for such patients typically has been noted to be 29.2 months (range 6–52 months) [78].

## Surveillance

Surveillance after ureteroscopic treatment of upper tract neoplasms is essential because of the high local recurrence rate in the ipsilateral renal unit and the bladder. Almost every paper reviewing experience with this treatment has cautioned that endoscopic surveillance is necessary. Similar to surveillance for bladder cancer, cystoscopy in UTUC patients is performed every 3 months for the first year, every 6 months for the second year, and yearly thereafter. Evaluation of the upper tracts for new or recurrent tumors can be maintained radiographically or with diagnostic ureteroscopy. It is important to note that ureteroscopy is the most sensitive technique to evaluate the upper tract and should be used routinely in follow up surveillance. Keeley and colleagues [70] found that the sensitivity of retrograde ureteropyelography for detecting recurrent upper tract tumors was only 25% in patients with UTUC history undergoing strict ureteroscopic surveillance. In another series [85], urinalysis, voided cytology, and retrograde ureteropyelography were compared in patients with ureteroscopically visualized and treated tumors. None of those tests could accurately and routinely detect tumors as well as endoscopic findings, which were defined as the gold standard. There was a high specificity of bladder urine cytology and urinalysis, which do support their use. If they are abnormal, earlier endoscopy should be undertaken. At this time, the role of FISH in detecting recurrent UTUC appears to be minimal.

Various surveillance protocols have been proposed. Some authors recommend excretory urography or retrograde ureteropyelography at intervals of 3–6 months with ureteroscopy reserved only when specifically indicated. However, the greater sensitivity of direct endoscopic inspection must be recommended as the preferred technique for surveillance. Ureteroscopy is continued at intervals of 3 months until the upper tract is clear, at which time the patient is examined ureteroscopically at 6 month intervals. Cystoscopy and cytology with urinalysis are continued at intervals of 3 months during the first 2 years (Table 50.5). Evaluation of the contralateral collecting system with retrograde pyelography should be performed at least yearly and possibly at each 6 month interval. Cross-sectional imaging with contrast, as tolerated by the patient's renal function, should be performed yearly to rule out locally advanced, extra-luminal disease.

## Complications

Complications can occur with any ureteroscopic procedure but there are some that appear to be specific to ureteroscopic tumor treatment. Many of the problems related to dilation of the ureterovesical junction can be avoided by the use of small-diameter rigid and flexible ureteroscopes. Electroresection is rarely used, and therefore the complications inherent in that procedure are avoided. With any of the techniques commonly used, electrocoagulation, laser coagulation, or resection with a neodymium:YAG or holmium:YAG laser, there remains

**Table 50.5** Surveillance.

| Interval | Action |
|---|---|
| 3 month intervals | Cystoscopy<br>Cytology |
| 6 month intervals (after tumor-free) | Ureteroscopy |
| 6 or 12 month intervals | Imaging of contralateral kidney (IVP or retrograde) |
| 12 month intervals | Cross-sectional imaging (CT or MRI) |

**Table 50.6** Strictures after ureteroscopic treatment of UTUC.

| Reference | No. of patients | Stricture | % |
|---|---|---|---|
| Suh et al. [71] | 16 | 2 | 12.5 |
| Daneshmand et al. [36] | 30 | 5 | 16.7 |

| Sowter et al. [73] | 40 | 4 | 10.0 |
| Chen et al. [86][a] | 139 | 19 | 13.7 |
| Overall | 260 | 33 | 12.7 |

[a] Combined series to 2001.

a risk of stricture from scarring of the ureter or an infundibulum. A review of complications from published series of ureteroscopic treatment of upper tract tumors indicates a ureteral stricture rate of 13% which is considerably higher than the less than 1% seen for stone treatment [86]. This may be an inherent risk of ureteroscopic tumor treatment, since the ureter itself is specifically traumatized with the treatment of the neoplasm. In comparison, damage to the ureteral wall during stone treatment is diligently avoided (Table 50.6).

Perforation remains a strong theoretical risk. However, reported series have not shown any strong propensity toward intraluminal tumor dissemination, implantation, extraluminal tumor, or tumor extension [55].

## Adjuvant therapy

Adjuvant chemotherapy or immunotherapy is an attractive option in the treatment of UTUC particularly because of the high recurrence rate. Due to the rarity of UTUC, no prospective, randomized trials have ever proven the efficacy of Bacille–Calmette–Guerin (BCG) or mitomycin C (MMC) as intraluminal adjuvant therapy following endoscopic management. Thus far, the literature offers mostly retrospective, single-institution, non-randomized case control studies containing relatively small numbers of patients with heterogeneous tumors with both ureteroscopic and percutaneous treatment approaches. Furthermore, no method of delivery to the upper tract has ever been standardized and these range from slow infusions via PCN tubes and ureteral catheters to passive application to the upper tract by bladder infusion with a stent. Two of the largest retrospective series published to date showed no benefit in terms of local recurrence rates in those given MMC with up to 63 months' mean follow-up [79] and those given BCG with up to 61 months' mean follow-up [87]. Thus, adjuvant therapy with either BCG or MMC has been seen to be feasible, with relatively low side effects, but efficacy has not been demonstrated. The safety and potential advantages of adjuvant therapy have been suggested in several short series but this treatment has no proven role.

## Cost of treatment

The application and the need for endoscopic resection and surveillance for upper tract tumors have raised concerns regarding the costs of this management. Pak and colleagues [75] examined the direct costs of renal-sparing conservative measures versus nephroureterectomy and subsequent chronic kidney disease or end-stage renal disease. In a cohort of 57 patients with a minimum follow-up of 2 years, renal preservation was 81% with CSS of 94.7%. On examination of Medicare payments, even the worst-case scenario of a solitary kidney with recurrences at each follow-up for 5 years versus nephroureterectomy and dialysis for the same period would save over US$250 000. This same savings could alleviate the expense of five cadaveric renal transplantations.

## Familial neoplasm of the upper urinary tract

Hereditary nonpolyposis colorectal cancer syndrome (HNPCC), also known as Lynch syndrome (LS), is an autosomal dominant genetic disorder which is characterized by germ-line mutations in DNA mismatch-repair genes, including *MSH-2*, *MLH-1*, *MSH-6*, and *PMS-2*. The syndrome is associated with predisposition to colorectal cancer and extracolonic tumors, especially the endometrium, but also including the breast, the ovary, and the upper urinary tract. An international retrospective cohort study performed by the world's largest LS research centers determined the lifetime risk of UTUC development in LS carriers was 8.4% but on further risk stratification was noted to be as high as 28% in men with *MSH-2* mutations with peak age of diagnosis between 50 and 70 years of age [88].

Observational studies suggest that the clinical behavior of UTUC in LS patients differs from sporadic cases of UTUC. Crockett et al. examined the Creighton University HNPCC database and found 39 patients with UTUC, the majority of who had confirmed mutational analysis [89]. When compared to sporadic UTUC cases, LS patients with UTUC present were on average 8 years younger, had a greater tendency towards ureteral tumor location versus intrarenal location, and had a slight female preponderance. A series of UTUC patients with *MSH-2* mutations treated with ureteroscopy and laser ablation has been reported [90]. Similar to Crockett's report, these patients were relatively young at presentation at a mean age of 56.5 years and demonstrated a greater tendency for ureteral lesions. This series had a notable rate of metachronous bilateral UTUC (6/13) with a mean time of 49 months between eventual bilateral UTUC development. Although selection bias in this small series must be taken into account, the risk for bilateral disease in this population must be seriously considered. Furthermore, given the relatively younger age at presentation, conservative management with endoscopic treatment should be entertained as first line therapy whenever clinically feasible [89–91]. Panel recommendations have been put forth suggesting annual urinary analysis in LS carriers with three or more red blood cells per high-powered field as an initiator for further work-up. Although routine imaging was not recommended in every case, strong consideration should be given to CT urogram, particularly in those patients already undergoing periodic cross-sectional imaging for other malignancies especially when *MSH-2* carrier status exists or family history of UTUC is present [92].

## Benign neoplasms

Benign urothelial neoplasms are rare in the renal pelvis and ureter. Many individual cases or short series have been reported and include fibroepithelial polyps, inverted papillomas, and hemangiomas as well as the more commonly noted ureteritis cystica.

Fibroepithelial polyps (FEPs) are mostly benign ureteral luminal lesions originating from the mesodermal components of the ureteral wall and are covered in otherwise normal urothelial epithelium. Very rarely they are associated with UTUC [93] and therefore routine pathologic analysis is required for a complete evaluation. FEPs typically appear in young patients as a smooth pedunculated mass in the upper urinary tract, often occurring at the ureteropelvic junction with polyp length ranging from 0.5 to 4 cm [94], although longer FEPs have been reported. Historically, these lesions have been treated by open surgical resection. However, the availability of small ureteroscopes and appropriate biopsy or resection devices, such as used for UTUCs have permitted ureteroscopic diagnosis and treatment. With increasing use of flexible digital ureteroscopes, the stalks of these FEPs are more clearly appreciated than ever, allowing for laser resection with holmium laser and complete removal with minimal trauma to the ureteral surface [95]. Follow-up after treatment is required only to confirm healing without significant stricture.

Inverted papillomas have also been considered a benign lesion, although there has been concern because of the association with UTUC and the difficult histopathologic diagnosis. The most common presentation has been with hematuria [96]. However, they can also cause obstruction with hydronephrosis. Endoscopically, they appear as a smooth mucosal based neoplasm. Often, there is a relatively narrow base encompassing less than one-quarter circumference of the ureter. The lesions lack the papillary configuration of low-grade UTUC, but can be confused with a higher-grade lesion. Endoscopic biopsy is a crucial diagnostic study. It is particularly helpful to excise the entire lesion [97]. Follow-up should be maintained both to confirm the patency of the urinary tract and because of the possible association with new UTUC. These neoplasms can be treated adequately ureteroscopically.

## Conclusion

Ureteroscopy plays a central role in the diagnosis and treatment of UTUC. Larger lesions may require a percutaneous approach. Lesions that are more extensive, high-grade, or unable to be controlled endoscopically require nephroureterectomy, which can usually be performed laparoscopically.

## Introduction

Advances in technology, instrumentation, and techniques have changed the practice of urology, especially over the past two decades. One of the areas of major impact has been the treatment of ureteropelvic junction obstruction (UPJO), which is defined as an anatomic or functional impedance of urine flow from the renal pelvis into the ureter [1] (Figure 51.1). This condition can be congenital or acquired, the congenital form being the more common. UPJO, although relatively uncommon, warrants prompt attention to alleviate symptoms and prevent deterioration of renal function. Several factors can play roles in the development of UPJO, including intrinsic aperistalsis of the involved ureteral segment, crossing aberrant vessels causing direct compression of the ureter, renal stone disease, and previous surgical or endourologic manipulation.

The advent of smaller-caliber endoscopes [2], and development of laparoscopic reconstructive techniques, laser technology, and robotics has diversified the treatment options for this condition.

Although the efficacy, and decreased morbidity, hospital stay, and need for analgesia with endopyelotomy have been clearly demonstrated, several issues have still not been completely resolved. Should patients be managed initially by the ureteroscopic approach? What are the exclusion criteria for these endoscopic procedures? What are the relative merits of antegrade versus retrograde approaches? In the era of minimally invasive laparoscopy and robot-assisted surgery, is there still a role for retrograde ureteroscopic endopyelotomy?

In this chapter we discuss the technique and results at our institution for retrograde ureteroscopic endopyelotomy for the treatment of UPJO.

## History

Several reconstructive procedures have been described for the management of UPJO since Trendelenburg's first description of such a procedure in 1886. Open surgical correction was the only mode of treatment for this condition before the introduction of endoscopic and laparoscopic techniques, and has been considered the gold standard of treatment for this condition, with success rates of over 90% [3]. However, associated morbidity is not unusual with open surgery. Specifically, there is fistula formation in 2.6% of patients, stricture of the ureteropelvic junction (UPJ) in 2.4%, and the need for nephrectomy in 3.2% [4].

The present-day endourologic approach to the management of UPJO can be traced back to the original descriptions of Albarran, Keyes, and Davis. Albarran did the first endosurgical repair of the UPJO in 1903, which actually described a ureterotome externe [5]. Keyes performed a similar procedure successfully in 1915 [6]. Both the antegrade and retrograde endopyelotomy follow the concept of Davis's intubated ureterotomy, first described by Davis in 1943. In 1985, Bagley et al. reported a combined percutaneous and flexible ureteroscopic approach for the management of an obliterated UPJ [7]. Wickham and Kellet described the first ureteroscopic pyelolysis of the UPJ in 1983 [8], and this was repeated by Inglis and Tolley in 1986 [9]. Thomas et al. described their experience of ureteroscopic endopyelotomy in which pre-stenting was performed to facilitate ureteroscopy in 1996 [10]. A single-setting, one-stage procedure was subsequently described by Soroush and Bagley in 1998 [11].

There are now multiple different options for the treatment of UPJO, including antegrade nephroscopic

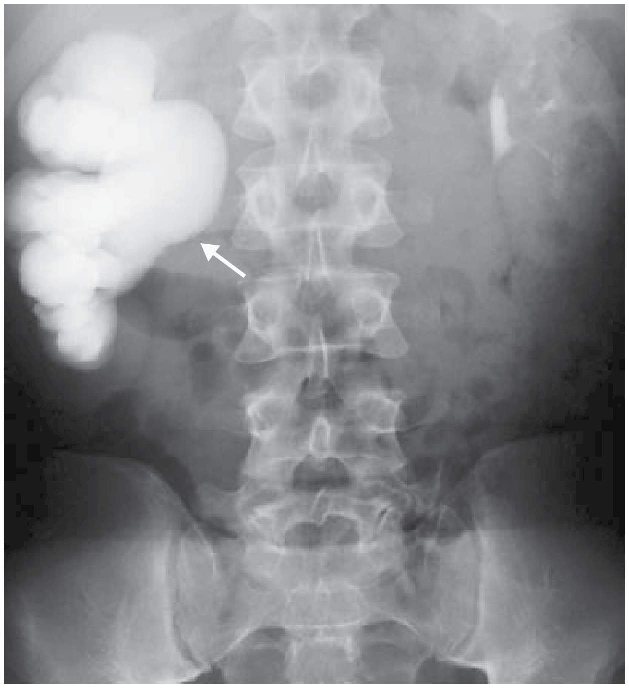

**Figure 51.1** Intravenous pyelogram of a right ureteropelvic junction obstruction (arrow).

endopyelotomy, retrograde ureteroscopic endopyelotomy, Acucise™ (Applied Medical, Rancho Santa Margarita, CA, USA), and laparoscopic and robot-assisted pyeloplasty, as well as the traditional open surgical pyeloplasty [12]. As mentioned above, open surgical dismembered pyeloplasty has been considered the gold standard for the treatment of UPJO, with success rates of over 90%. However, many institutions have considered endopyelotomy a possible first-line therapy option for the treatment of this condition [13–16].

Currently, a retrograde endopyelotomy can be performed in three ways: (i) using a rigid ureteroscope and a cold-knife, electrocautery, or holmium laser incision; (ii) using a flexible ureteroscope and electrocautery or laser incision; and (iii) in rare select cases, using a balloon with a cutting wire (Acucise) [15]. The technique of dilation and cold-cut incision with a peripheral cutting balloon, which was originally designed for angioplasty, had been reported mainly for ureteral strictures other than UPJO [17–19]. For UPJO, a recent retrospective case series was described in infants under 18 months of age [20]. This has not yet been reported in literature for adult patients with UPJO. It must be mentioned that the use of Acucise is not recommended for primary UPJO because of incidences of hemorrhage following use of this device.

Different series have reported success rates for retrograde ureteroscopic endopyelotomy to be in the range of 73–90% [10, 11, 21–24]. As compared with other treatment options, ureteroscopic retrograde endopyelotomy is less invasive, requires less operating room time, enables the procedure to be performed on an outpatient basis or with a very short hospital stay, and is associated with a shorter convalescence period [1, 13, 25–29]. Also, the initial report of ureteral stricture formation because of thermal injury from transmission of the electrocautery current has been eliminated with the use of insulated ureteroresectoscopes and electrocautery and rigid or flexible ureteroscopes with holmium laser fibers [30]. With the miniaturization of ureteroscopes, the use of the rigid resectoscope is no longer advised.

## Patient selection and preoperative preparation

The presumptive clinical diagnosis of UPJO can be evaluated and/or confirmed with a renal ultrasound, intravenous pyelogram (IVP), diuretic renal scan, retrograde pyelogram, computed tomography (CT) scan, Whitaker test, or with a combination of these, as is clinically indicated. The renal scan, besides aiding in the diagnosis of a UPJO, gives a quantitative differential renal function, which can be used to choose the best treatment option and, further, to allow for follow-up evaluation of the renal function.

A high-resolution spiral CT angiography is highly recommended to assess for the presence of an aberrant crossing vessel. For practitioners with experience and access to endoluminal ultrasound equipment, it can also be used to identify crossing vessels [31]. The UPJ area can also be evaluated ureteroscopically for the presence of pulsations before performing the endopyelotomy incision.

Although ureteroscopic retrograde endopyelotomy is applicable to most patients with UPJO, there are some absolute and relative exclusion criteria. Among the absolute contraindications are patients with active infection and bleeding diathesis.

Patients with concurrent renal calculi and UPJO, and patients with a nephrostomy tube in place, should be treated with an antegrade approach so that both the renal stone and the UPJO can be managed in a one-stage procedure. Patients with a relatively long length of obstruction, usually greater than 2 cm, are best managed either with open surgical, laparoscopic, or robot-assisted techniques. Patients with ipsilateral differential renal function of less than 20% and severely decreased parenchymal thickness can be given a trial of drainage and re-evaluation [15] or should be offered a laparoscopic simple nephrectomy for a poorly functioning or nonfunctioning kidney. Patients with massive hydronephrosis should be treated with dismembered pyeloplasty, either open surgical, laparoscopic, or robot-assisted, because of the need for trimming and reduction of the redundant renal pelvis. Controversy exists with regard to patients with high insertion of the UPJ and crossing vessels. Although once considered a contraindication because of poor results, published series report that the type of ureteral insertion has no significant impact on the outcome of endopyelotomy [32], and that patients with crossing vessels had long-term success with retrograde endopyelotomy [14]. We routinely perform laparoscopic robot-assisted pyeloplasty in both cases with a high insertion UPJO or a known crossing vessel [12]. In the case of recurrent UPJO after pyeloplasty in adult patients, a trial of retrograde endopyelotomy should be considered as it has been noted to have success rates greater than 80% in such cases [33]. Lastly, patients with known intractable stent intolerance should be considered candidates for either an antegrade endopyelotomy or an open pyeloplasty with a nephrostomy tube, and not for ureteroscopic endopyelotomy.

Once the surgeon and patient have decided on the retrograde approach for management of a UPJO, an indwelling ureteral stent is usually placed to drain the obstructed renal unit for 1–2 weeks. This procedure not only drains the obstructed renal unit, but also stabilizes its renal function, dilates and straightens the UPJ, and facilitates subsequent passage of the ureteroscope into the renal pelvis. Above all, preoperative placement of the stent allows evaluation of any degree of stent intolerance and may identify improvement of renal function after drainage.

### Informed consent

On the day of the scheduled endopyelotomy, any final questions are answered, and an informed consent is obtained after explaining and discussing with the patient the expected outcomes and benefits of the procedure (e.g. improved renal drainage, preservation of renal function, diminished risk of calculus and infection, minimally invasive procedure), its associated risks or complications (bleeding, infection, possibility of conversion to open surgery, recurrence, etc.), and the other minimally invasive treatment options available. Patients are informed that postoperative evaluations may show some residual pelvicaliectasis, especially in those with long-standing UPJO.

## Step-by-step operative technique

The required instrumentation is listed in Table 51.1. After either a general or a spinal anesthesia, the patient is placed in the lithotomy position. Caution is taken so that all pressure points are well cushioned, and antiembolic

stockings are used in high-risk patients. With the use of a cystoscope, and under fluoroscopic guidance, a retrograde pyelogram is performed to confirm the length of the UPJO segment, and subsequently a super-stiff guidewire is passed and coiled into the renal pelvis. If the patient had a previously placed indwelling ureteral stent, it is removed and used to pass the guidewire prior to removing the stent. A retrograde pyelogram can assess for any resolution of hydronephrosis and can be used as a prognostic indicator.

The next step varies depending on whether the endopyelotomy is done with electrocautery through a ureteroresectoscope or whether a holmium laser is used through a modern rigid, semirigid, or flexible ureteroscope. In regions where the holmium laser is not available, an insulated electrocautery electrode can be used to incise using the cutting current.

## Holmium:YAG laser ureteroscopic endopyelotomy

A 7.5 Fr self-dilating rigid, semirigid, or flexible ureteroscope is passed alongside the super-stiff guidewire using generally accepted ureteroscopic techniques. A balloon dilator can be passed over the guidewire and the ureteral orifice dilated in the case of difficulty advancing the ureteroscope within the ureter. If necessary, another guidewire can be passed through the ureteroscope and the narrow area subsequently balloon dilated.

Once at the UPJ, this is first inspected for the presence of any transmitted pulsations. A 365 μm holmium laser fiber, when using a rigid or semirigid ureteroscope, or a 200 μm fiber in the case of a flexible ureteroscope, is passed through the working channel of the ureteroscope. At a setting of 1.5–2.5 J and a frequency of 10–15 Hz, the UPJ is incised under direct vision either laterally or posterolaterally to avoid the risk of injuring any unsuspected crossing vessel. The incision is carried on until periureteral fat is seen and the UPJ is wide enough to permit easy passage of the ureteroscope into the renal pelvis (Figure 51.3).

After hemostasis of any venous bleeding is performed, the laser fiber and ureteroscope are removed. The UPJ area is dilated up to 24 Fr using a balloon dilator under fluoroscopic guidance. The concept of balloon dilation of the UPJ is based on Davis' intubated ureterotomy, in which the incised and dilated ureteral fibers regenerate around the ureteral stent over a 6 week period [6] (Figure 51.4).

The balloon dilator is then removed. An endopyelotomy stent is placed under fluoroscopic control, leaving the 14 or 10 Fr end at the UPJ (depending on the stent

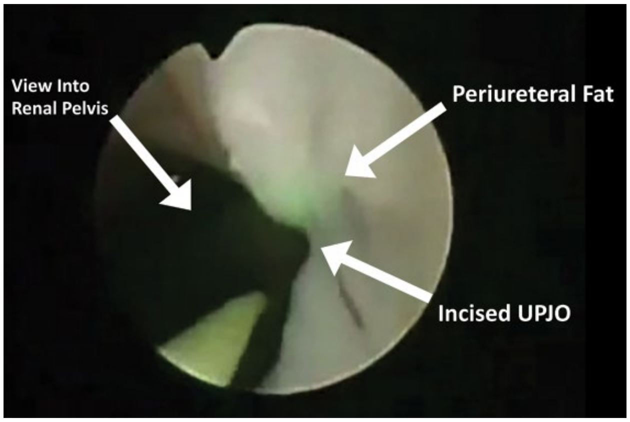

**Figure 51.3** Periureteral fat seen after the ureteropelvic junction was incised with a holmium laser.

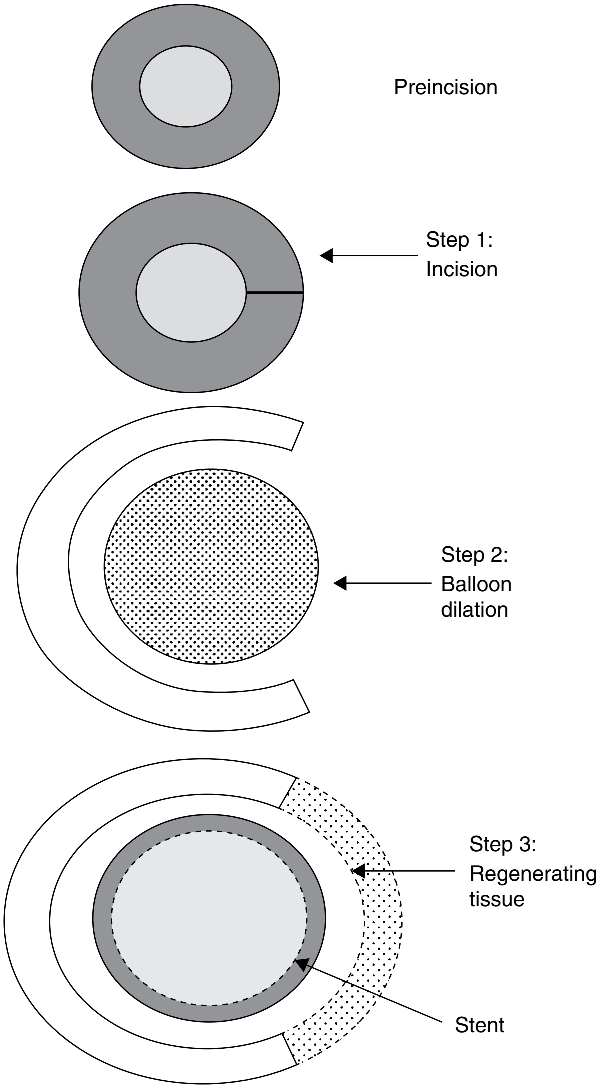

**Figure 51.4** Tissue regeneration after incision and balloon dilation.

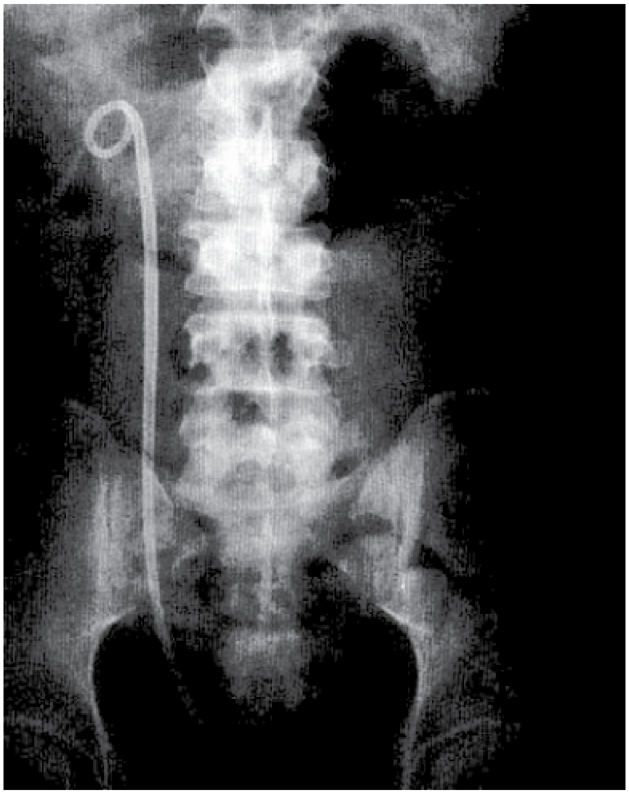

**Figure 51.5** Endopyelotomy indwelling stent in place after ureteropelvic junction obstruction incision.

used) and the 7 Fr end coiled in the bladder (Figure 51.5). Alternatively, a 7 or 8 Fr double-J ureteral stent can be left in place. The authors recommend using a ureteral stent one size longer than anticipated to prevent downward migration of the renal coil into the incised UPJ. If the stent is malpositioned, this can lead to leakage of urine into the retroperitoneal space with formation of a urinoma.

As the ureteral stent can reflux urine from the bladder to the incised UPJ, an indwelling Foley catheter is placed to drain the bladder for 48 hours. This helps to maintain a low-pressure system in the urinary uract and to prevent urinary reflux through the ureteral stent into the incised UPJ, which also may leak into the retroperitoneal space, possibly causing formation of a urinoma.

## Ureteroscopic endopyelotomy with electrocautery

A 5 Fr open-ended catheter is passed over the super-stiff wire. The open-ended catheter works as an insulator, preventing contact with the electrocautery element, and avoiding transmission of current along the length of the guidewire if contact is made. Also, once the wire is removed, the open-ended catheter may serve to continuously drain the renal pelvis of the irrigant used during the procedure.

The 11.5 Fr ureteroresectoscope is passed directly alongside the insulated guidewire with the cold knife in place. The electrocautery element is right-angled and would impede vision if placed during the insertion of the ureteroresectoscope [1]. If there is difficulty accessing the ureteral orifice or the intramural ureter, a balloon dilator can be passed over the guidewire to dilate the area. If there is resistance advancing the ureteroresectoscope along the ureter proximal to the UPJO, a smaller self-dilating ureteroscope can be passed to passively dilate the ureter and to inspect for the cause of the narrow area. If necessary, another guidewire can be passed through the self-dilating ureteroscope and the narrow area is balloon dilated.

Once at the UPJ, the cold-knife working element is exchanged for the electrocautery element. Either water or 1.5% glycine solution is used as the irrigant during monopolar electrocautery for incision.

The UPJ is first inspected for the presence of any transmitted pulsations, and then incised laterally, between 8 and 9 o'clock on the right and between 3 and 4 o'clock on the left. Short and shallow strokes should be performed, and aggressive and deep incisions should be avoided. Any bleeding site is controlled by means of spot electrocoagulation. The incision is carried down until periureteral fat is seen, and the ureteroresectoscope enters the renal pelvis with ease.

The ureteroresectoscope and the open-ended catheter are removed. The rest of the subsequent steps, balloon dilation, stenting, and Foley catheter drainage, are the same as described above for the holmium:YAG laser endopyelotomy. As mentioned above, if the holmium laser is not available, then a flexible insulated electrocautery electrode can be used instead.

### Postoperative care

The vast majority of patients are discharged either the same day or within the first 24 hours following the procedure. Oral antibiotics, usually fluoroquinolones, are given for 3–5 days. Oral antispasmodics and/or oral anticholinergics are given as needed in case of irritative bladder symptoms. The Foley catheter is removed, often by the patient, after 48 hours. The ureteral stent is removed cystoscopically in clinic in 6 weeks.

Diuretic MAG3 renal scans or IVP are performed 4 weeks after ureteral stent removal. Patients are followed-up with renal ultrasound or renal scan every 4–6 months during the first year and yearly thereafter or as needed.

Success following endopyelotomy is measured by evaluating improvement of the function and drainage of the involved kidney and alleviation of symptoms. After correction of the obstruction at the UPJ, postoperative radiographic images from an IVP or CT scan often show residual pelvicaliectasis resulting from long-standing obstruction and dilation that may not completely resolve.

## Results

We analysed the outcome of 139 consecutive patients who underwent retrograde ureteroscopic endopyelotomy at Tulane University Health Sciences Center between 1989 and 2002. These patients included seven pediatric patients, four solitary kidneys, two horseshoe kidneys, and one ptotic kidney.

The average postoperative hospital stay was less than 24 hours. Seventy-nine percent of the patients were discharged home on the same day, and 97% of them within 24 hours. Of the 139 patients, 32 (23%) required subsequent procedures to treat recurrence of obstruction, showing an overall long-term success rate for retrograde ureteroscopic endopyelotomy of 77%. Fourteen of these patients (10%) required major open or laparoscopic surgical intervention, including nephrectomies for severe hydronephrosis and nonimprovement in renal function in three (2%) cases, emergent nephrectomy for severe bleeding in one (0.7%), dismembered pyeloplasties in eight (5.7%), and spiral flap pyeloplasties in two (1.4%).

Eighteen (12.9%) patients required minor procedures, which included cystoscopy and balloon dilation of the UPJ in 13 (9.3%), repeated retrograde endopyelotomy in four (2.8%), and long-term indwelling stent exchange in one (0.7%). There were no ureteral strictures secondary to manipulation or the earlier use of the larger ureteroresectoscope in our series.

After analysing the failures of treatment in this series, two factors were obviously associated with poor results (no improvement of symptoms, drainage, and function after endopyelotomy): (i) a long-standing obstruction with a decrease in ipsilateral renal function of less than 20% of the total renal function and (ii) a severely dilated renal pelvis, which did not improve on drainage with an indwelling ureteral stent.

After evaluation of these results, we conclude that patients with patulous redundant renal pelvis and borderline salvageable renal function should be considered candidates for alternative treatment modalities, such as open or laparoscopic/robotic pyeloplasty or nephrectomy, rather than endopyelotomy.

## Complications

Since its initial description by Young in 1912, retrograde ureteroscopy has come a long way and has gained widespread acceptance as an option for the treatment of multiple pyeloureteric conditions. Further advances in technology have led to the introduction of smaller-caliber ureteroscopes with the capacity to accommodate accessory instruments necessary to perform diagnostic and therapeutic upper urinary tract procedures.

As with ureteroscopy, the complications and adverse events associated with retrograde ureteroscopic manipulation of the ureter have decreased dramatically in the past two decades. Smaller-caliber ureteroscopes, the advent of laser technology, improved paraphernalia, and, above all, experience in the procedures, should be given credit. Although these advances have decreased the need for open ureteral surgery, iatrogenic injury can still occur with the endoscopic technique. Possible iatrogenic complications of ureteroscopy include ureteral perforation, stricture, false passage, ureteral avulsion, bleeding from the ureteral mucosa or adjacent structures, infection, and sepsis. Multiple studies have reported the overall complication rate of ureteroscopy to fluctuate between 1 and 15% [34–36]. Complication rates have substantially decreased following introduction of smaller-caliber rigid and flexible ureteroscopes.

The reported incidences of pain, fever, false passage, and urinary tract infection were 5.5, 1.4, 0.4, and 1.6%, respectively, in one large ureteroscopy series [37].

Other complications associated with incision of the UPJ can include bleeding from adjacent aberrant vessels, stent migration through the UPJ incision, and UPJO recurrence. Significant bleeding requiring emergent nephrectomy or selective angioembolization is another possible complication that justifies the need for vascular or three-dimensional (3D) radiographic studies to identify aberrant vessels. The use of a complete lateral incision at the UPJ helps to prevent injuries to those vessels, based on detailed anatomical studies of renal vascular anatomy [38].

Minor complications of retrograde ureteroscopic endopyelotomy include proximal stent migration, stent intolerance, minor bleeding, and urinary tract infection after manipulation. Most of these complications are alleviated after removal of indwelling ureteral stents. The routine use of antispasmodic and anesthetic drugs after surgery improves tolerance to the stent and decreases complaints from the patient.

## Current role of retrograde endopyelotomy

With the proliferation of robotic technology, robotic pyeloplasty has replaced ureteroscopic endopyelotomy as the primary treatment option for UPJO. In these institutions, retrograde endopyelotomy is reserved for initial management of any UPJO recurrence following robotic pyeloplasty. However, the indications for retrograde endopyelotomy have not changed in institutions where laparoscopic and robotic pyeloplasty are unavailable.

## Comparison of treatment approaches and conclusions

Multiple endourologic and open surgical techniques are now available for the treatment of UPJO. The choice of technique relies primarily on the urologist's experience with each procedure, available equipment, and the need to perform another concomitant procedure.

Antegrade endopyelotomy requires expertise in percutaneous renal surgery, with detailed knowledge of the intrarenal anatomy and adequate experience in "real-time" two-dimensional fluoroscopic imaging. This is the preferred technique when treating concomitant intrarenal calculi, but it is also associated with a larger potential for complications and morbidity. The occurrence of pneumothorax, adjacent organ trauma (i.e. bowel, spleen, liver), and hydrothorax are possibilities that need to be explained to the patient prior to the surgery. Antegrade and retrograde endopyelotomy share the potential for hemorrhage from injury to aberrant crossing vessels; however, antegrade access may also be associated with hemorrhage from the percutaneous renal tract and with a higher risk of infection owing to external urinary drainage through the percutaneous nephrostomy tube.

Acucise retrograde endopyelotomy is no longer popular, but, if performed, relies on fluoroscopic imaging and not on direct visualization during cutting of the UPJ. High-quality fluoroscopic imaging is critical for optimal electrode placement. Short-term success rates of this procedure have been comparable to those obtained with retrograde ureteroscopic endopyelotomy and range from 66 to 84% [39]. Extreme caution should be exercised when using this technique in the presence of aberrant crossing vessels. Preoperative CT scan with angiographic phase and 3D reconstruction has been shown to be adequate to collect information regarding periureteral vasculature at the level of the obstruction [40]. Incision at the lateral position of the UPJ should minimize the risk of vascular injury while performing this procedure. Use of this technique has dramatically decreased because of lower success rates noted with long-term follow-up [41].

Multiple different indwelling stents can be used to maintain patency of the UPJ after an endopyelotomy. At our institution we use a 7 or 8 Fr double-J ureteral stent with postoperative results similar to those obtained with endopyelotomy stents. It is always important to use an indwelling stent one size longer than anticipated in order to avoid downward migration of the stent that could compromise endopyelotomy healing.In many high-volume centers, laparoscopic and robotic pyeloplasty has supplanted retrograde ureteroscopic endopyelotomy as the first-line treatment for UPJO because of good long-term outcomes (i.e. greater than 90%), comparable to those of open pyeloplasty. While robotic pyeloplasty has replaced retrograde ureteroscopic endopyelotomy as our first-line treatment for most symptomatic UPJO, it is our belief that retrograde ureteroscopic endopyelotomy continues to have a place in providing a safe and adequate treatment for patients suffering from a short-segment UPJO with good renal function and non-patulous renal pelvis. With the advent of smaller scopes and devices, this technique has evolved to include larger children as possible patients. Adherence to strict endourologic principles and direct visualization makes retrograde ureteroscopic endopyelotomy a safe and effective treatment modality. Furthermore, this procedure has a short learning curve and can be performed in almost all general hospitals where ureteroscopy is performed.

Lastly, this procedure should always be part of a urologist's treatment armamentarium, because adult patients who have failed laparoscopic, robotic, or open surgical pyeloplasty can be managed with ureteroscopic retrograde endopyelotomy as a secondary procedure.

# Endoscopic Management of Mid-ureteral Obstruction

*Samuel Abourbih & D. Duane Baldwin*

*Loma Linda University Medical Center, Loma Linda, CA, USA*

## Introduction

Strictures of the ureter are challenging to diagnose, technically difficult to treat once diagnosed, and associated with significant psychological overlay due to their frequent iatrogenic etiology. Although sometimes successfully treated with a single endoscopic procedure, mid-ureteral strictures tend to recur, and may lead to renal loss if the obstruction is not expeditiously diagnosed and relieved. Mid-ureteral strictures are anatomically, physiologically, and surgically distinct from both proximal and distal ureteral strictures. Therefore, the endourologist must possess an intimate understanding of ureteral anatomy and physiology to avoid injury to the ureter, and to provide definitive management for these injuries when they do occur. This chapter will review strictures of the mid ureter, including the anatomy, prevention, diagnosis, and treatment.

## Anatomy

The adult ureter is 25–30 cm long and 1.5–6 mm wide in its unobstructed, physiologic state [1]. The course of the ureter in the retroperitoneum is relatively constant, and is generally found just lateral to the transverse processes of the lumbar vertebrae (Figure 52.1). Knowledge of the anatomical relationships of the ureter may prevent iatrogenic injury [1]. Posterior to the proximal ureter, the genitofemoral nerve runs along the psoas muscle [2, 3]. Anteriorly, at the level of the kidney lower pole, the ureter is crossed by the gonadal vessels. In close proximity to the abdominal ureter is the sigmoid mesocolon [4].

Just below the pelvic brim, the ureter crosses over the common iliac artery near its bifurcation. The iliac artery pulsations may serve as an important ureteroscopic landmark. The ureters then course inferoposteriorly, along the pelvic sidewall, anterior to the internal iliac artery and outside of the parietal peritoneum. The ureters then run anteromedially into the bladder [5]. The ureter is divided into three anatomic portions, with the middle portion overlying the bony pelvis. The ureter also has three anatomic narrowings including the ureteropelvic junction, the level where the ureter crosses the common iliac artery, and the intramural ureter [6].

Familiarity with the ureteral blood supply may prevent inadvertent devitalization during ureteral dissection. The ureter has a segmental blood supply from the aorta and renal, gonadal, common iliac, and internal iliac arteries. Above the pelvic brim, the arterial supply originates medially while it originates laterally below the brim [6].

Histologically, from inner to outer, the ureteral layers are the urothelium, mucosal vascular plexus, muscular layer, and adventitia. In the upper ureter, the inner muscular layer parallels the long axis of the ureter. The outer muscular layer has a circular or oblique orientation. The mid and distal ureter have an additional outer longitudinal layer. The adventitia contains vertically arranged arteries supplying the ureteric wall [6]. Dissection of the ureter should proceed outside these vessels to avoid compromising its blood supply. Preservation of these vessels will allow collateralization from other levels even if some blood supply must be sacrificed [7].

The venous drainage parallels the arterial supply. The lymphatic drainage of the ureter consists of the lateral aortic (lumbar), common iliac, external iliac, and internal iliac lymph nodes. The nervous supply of the ureter arises from adjacent renal, aortic, and hypogastric autonomic plexuses. Pain fibers enter the spinal ganglia and the spinal cord at segments T11 through L1 or L2, taking the same course as the sympathetic fibers [5].

## Classification and etiology of strictures

A ureteral stricture is a pathologic narrowing of the ureter, resulting in dilation of the urinary system proximal to that point with resultant delayed urine transit. Strictures may be extrinsic, intrinsic, or intraluminal. This classification system is valuable since the different types of obstruction may be treated differently. For example, intraluminal obstruction may be successfully treated by endoscopic ablation or removal of the obstructing agent, while extrinsic obstruction is difficult to treat endoscopically and requires drainage and treatment of the extrinsic etiology of the obstruction.

Strictures can also be classified as ischemic or non-ischemic. This definition is also clinically relevant because ischemic strictures may not respond as well to endoscopic procedures [8]. Strictures have also been classified as inflammatory versus non-inflammatory [9], but it is unclear if there is any clinical relevance to this classification system [10]. Table 52.1 lists the etiologies and classifications of ureteral obstruction.

Strictures often arise iatrogenically due to surgery, by clipping, suture ligation, thermal injury, or devascularization. Gynecological surgery is the most common cause of iatrogenic ureteral injury and hysterectomy is the leading procedural cause, occurring at a rate of 0.5–1.5% [10, 11]. Abdominal hysterectomy is more likely to lead to ureteral injury (2.2%) compared to vaginal hysterectomy (0.03%) [10]. Unfortunately only 13–66% of injuries are detected intraoperatively, with the remainder diagnosed postoperatively [10].

**Table 52.1** Etiologies of mid-ureteral strictures according different classifications.

| | | | | | Iatrogenic injury |

The incidence of ureteral injury from colon and rectum surgery is on the rise [4, 12]. The types of colorectal surgery most likely to injure the ureter are transverse colectomy (0.05%), right hemicolectomy (0.08%), proctocolectomy (0.26%), left hemicolectomy (0.28%), sigmoidectomy (0.33%), subtotal/total colectomy (0.35%), anterior resection (0.58%), and abdominoperineal resection (0.76%) [12]. Rectal cancer is the most common underlying disease associated with ureter injury at the time of colorectal surgery [12].

Urological surgery is another well-recognized cause of ureteral stricture. In the initial experience of endoscopic stone treatment, large-caliber ureteroscopes [13] and lithotrites like the electrohydraulic probe led to a major complication rate (defined as perforation, avulsion, or stricture) of 6.6% [14]. In the modern era, with the advancement of technology to include smaller, tapered, and more flexible ureteroscopes and instruments the stricture rate for uncomplicated ureteroscopy is 0.3–0.6% while the perforation rate for intact extraction of stones is 4% [15, 16]. The danger arises when these injuries are not recognized intraoperatively, and are associated with silent obstruction, risking renal loss. This concern has led the American Urological Association to recommend routine ultrasound of upper tracts following ureteroscopic manipulation for stone removal [17].

A long-standing, impacted, ureteral stone can also lead to ureteral wall damage and stricture formation (Figure 52.2). Roberts et al. reviewed 21 patients with long-standing ureteral stones (mean 8 months) [18]. After treatment, 24% developed strictures. The authors identified longer duration of impaction and iatrogenic ureteral perforation during ureteroscopy as risk factors for future stricture formation [18].

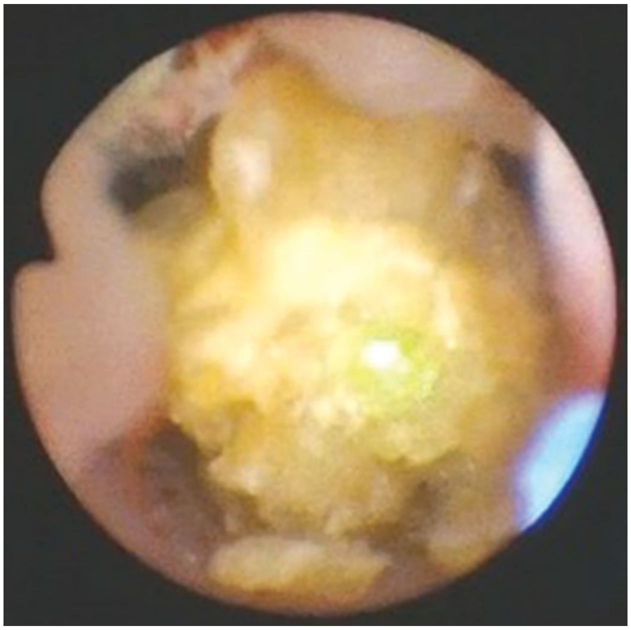

Figure 52.2 Impacted ureteral stone. Note mucosal edema and ingrowth around stone.

An entity called congenital mid-ureteral stricture represents a rare cause of mid-ureteral obstruction and may be confused with either ureteropelvic junction or ureterovesical junction obstruction. This highlights the importance of retrograde pyelography prior to treatment of ureteral strictures [19, 20]. Segmental excision is curative and the etiology may be chronic *in utero* ischemia at the level of the mid ureter because of the vascular watershed between the aorta and iliac vessels.

## Presentation

An injury to the mid ureter may present clinically in a variety of ways. In the case of acute iatrogenic ureteral transection the patient may be acutely septic while in the case of a ligated but intact ureter, the patient may present with ipsilateral flank pain, recurrent pyelonephritis, and/or an unexplained rise in serum creatinine. Urine extravasating into the peritoneal cavity may cause peritoneal irritation and findings of an acute abdomen. In contrast an incomplete stricture may be asymptomatic, and identified incidentally only upon abdominal imaging. In an international review of almost 2000 ureteroscopy patients, the majority of strictures were symptomatic but three (0.15%) were asymptomatic. The presence of pain after stent removal had a 64.3% positive predictive value and a 99.8% negative predictive value for stricture.

## Diagnosis

There are several methods available to assist the urologist in the evaluation of strictures (Table 52.2). One of the simplest and least invasive initial studies is ultrasonography. B-mode ultrasound will detect dilation of the renal pelvis and/or calyces although ureteral dilation is sometimes obscured by overlying structures or bowel gas. Using Doppler sonography the resistive index (RI), defined as [peak systolic velocity – end diastolic velocity]/peak systolic velocity, is generally less than 0.7 in an unobstructed system [21]. Although a RI above 0.75 is correlated with obstruction, compared to normal kidneys (RI 0.6) and healthy controls (0.58; $P < 0.05$) [22], a threshold RI of 0.7 has only a 44% sensitivity and 82% specificity for diagnosis of ureteral obstruction [23].

Historically intravenous pyelography was employed in the diagnosis of suspected ureteral injuries (Figure 52.3). This modality is still available in many centers, although

**Table 52.2** Diagnostic modalities used to evaluate mid-ureteral strictures. Costs are listed in US dollars.

| Modality | Advantages | Disadvantages | Sensitivity | Specificity | Cost |
|---|---|---|---|---|---|
| Computed tomographic (CT) urography | Superior spatial resolution<br>Non-invasive | Significant radiation source<br>Contrast reactions | High | High | $1565 |
| Magnetic resonance (MR) urography | No radiation<br>Ideal for diagnosing extrinsic causes | Poor ability to diagnose stones<br>Nephrogenic systemic fibrosis<br>Expensive, time-consuming | High | High | $2048 |
| Diuretic renography | Provides split function<br>Provides functional information regarding obstruction | Subjective interpretation<br>Inconsistent results | High | Medium to high | $1138 |
| Ultrasonography | No ionizing radiation<br>No need for intravenous contrast medium | Operator dependent<br>Image quality dependent on body habitus and overlying structures | Med to High | High | $410 |
| Whitaker test | Provides objective information regarding obstruction<br>Can identify bladder pressure abnormalities | Invasive<br>Unfamiliar to many radiologists | Medium | Low to medium | Variable |

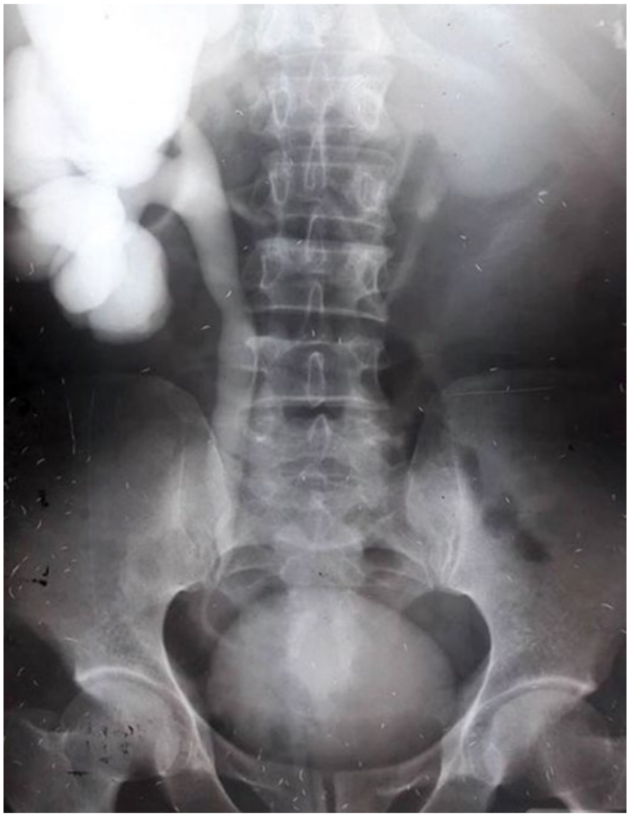

**Figure 52.3** Intravenous pyelogram showing abrupt narrowing of contrast at the level of the mid ureter. Courtesy Dr Mohamed Keheila and Dr Waleed Elsayed.

the results are not as sensitive or as specific as computed tomographic (CT) urography [24].

CT imaging represents the most common modality employed to evaluate ureteral obstruction. Unenhanced CT scanning is the gold standard for the initial evaluation of suspected nephrolithiasis [17], but does not reliably determine non-stone-related causes of ureteral obstruction. In such instances, CT urography provides superior spatial and contrast resolution by opacification of the collecting system [25] enabling it to detect stones, urothelial masses, and congenital anomalies. Disadvantages of CT urography include the need for intravenous contrast, which can lead to nephropathy (defined as a rise in serum creatinine of 0.5 mg/dl or 25%) and contrast allergy [26]. Risk factors for contrast nephropathy include renal impairment, diabetes, age, congestive heart failure, dehydration, multiple myeloma, and high-osmolality agents [26], and these risk may be mitigated by hydration, discontinuation of nephrotoxic agents, reduced contrast dose, *N*-acetylcysteine, and use of iso-osmolar or low-osmolality contrast medium. When precise anatomical details are required and intravenous contrast is contraindicated, CT pyelography can be performed by injecting contrast through a nephrostomy, or by direct needle puncture of the collecting system. In a study by Ghersin et al., CT pyelography successfully detected the cause of ureteral obstruction in 20/20 patients who failed first-line imaging [25].

Diuretic renography provides objective evidence regarding ureteral obstruction. In this procedure the patient is hydrated and challenged with furosemide (usually 40 mg intravenously), administered when the tracer peaks in the affected system. Obstruction is defined as the time required to clear half of the radionuclide (T½) greater than 20 minutes, while a T½ of <10 minutes is considered unobstructed. T½ times between 10 and 20 minutes are indeterminate [27]. However, if furosemide is given too early during the filling phase it may lead to a flat drainage curve and a false impression of poor drainage [28].

In addition, severe hydronephrosis and chronic renal insufficiency may lead to false positive results [28, 29]. It is also important to remember to place a bladder catheter in patients with vesicoureteral reflux, high bladder storage pressures, or those with indwelling ureteral catheters [28].

Magnetic resonance (MR) urography is also useful for identifying ureteral obstruction. Semins et al. compared MR urography in a 3-T scanner with HASTE sequences to noncontrast CT in colic patients [30]. MR had an 84% sensitivity for obstruction but identified a stone in only 50% of patients with stones on CT [30]. Specific situations where MR urography may be useful are in radiation-sensitive populations such as children, pregnant women (done without gadolinium), and patients with extensive prior radiation exposure. In an iatrogenically created ureter obstruction animal model the sensitivity and specificity of diuretic renal scintigraphy, MR urography, and ultrasound RI were 93.3 and 88.8%, 86.6 and 77.5%, and 86.6 and 77.5% respectively. However, no one modality was able to correctly predict all cases of obstruction-related apoptosis [31].

Antegrade and retrograde pyelography are familiar to most urologists, simple to perform, and the results are usually easy to interpret (see Figure 52.4). However, these techniques require radiation exposure and are invasive, usually requiring an anesthetic. These modalities provide the stricture severity, length, and potential etiology.

The invasive Whitaker test assesses whether hydronephrosis is obstructive by antegrade perfusion of the kidney with saline or dilute contrast at 10 ml/min. The pressure is measured simultaneously within the renal pelvis and bladder. Obstruction is diagnosed when the renal pelvis minus the bladder pressure is $>22\,\text{cmH}_2\text{O}$ [32]. This test may underdiagnose obstruction in the face of massive hydronephrosis [33]. Usually, the Whitaker test is performed when there is disagreement between other imaging modalities leading to ambiguity in the diagnosis [32].

Intraluminal ultrasound using a 12.5–30.0 MHz probe deployed in the ureter may provide information regarding the nature of the ureteral wall and periureteral tissues, and information regarding any associated foreign body (stone) within the ureter or periureteral tissues [34]. Also, a mixture of indocyanine green injected in a retrograde manner into the collecting system may help identify the location of a stricture and help to identify the diseased ureter (remains dark) from the healthy fluorescing ureter during robotic ureteroureterostomy [35].

## Stricture prevention

The best way to prevent mid-ureteral stricture disease is to use immaculate surgical technique and to preserve a robust ureteral blood supply. During ureteroscopy, the mid ureter is the most susceptible region for major ureteral complications including the highest rates of ureteral avulsion (0.3%) and perforation (1.6%) [36]. Small-caliber ureters occurring in small patients, children, young males, duplicated systems, and following radiation or inflammatory processes are at the highest risk for injury [37, 38]. In these situations prestenting may allow passive ureteral dilation for 1–2 weeks and reduce this risk [39]. Prestenting may also be beneficial prior to complicated abdominal or pelvic surgery where extrinsic pathology and inflammation may make ureteral identification difficult [40, 41].

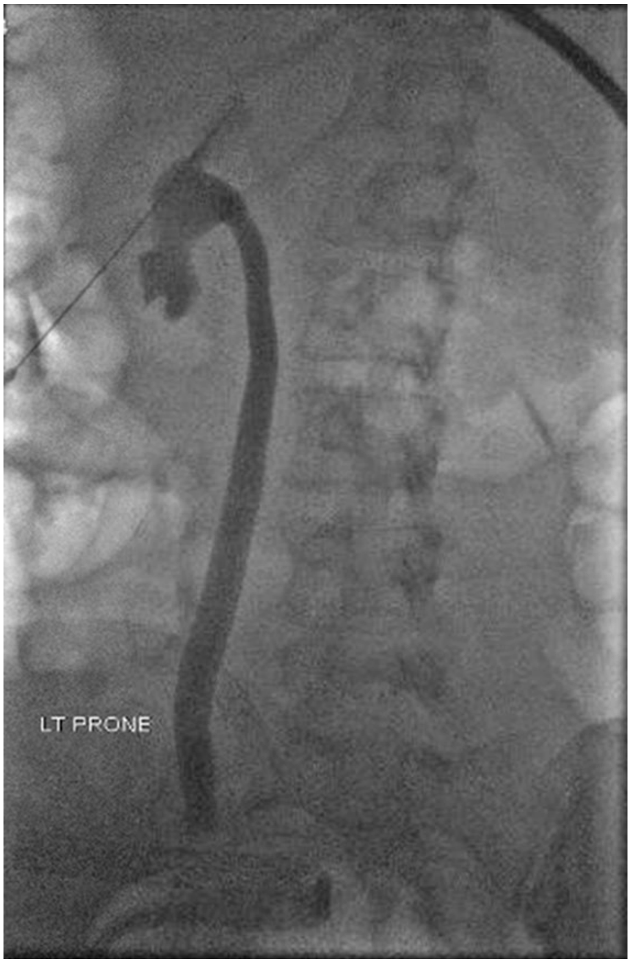

**Figure 52.4** Antegrade nephrostogram showing complete ureteral obliteration at the mid ureter.

Fluoroscopic stone identification over the dense bony pelvis is more difficult. Also, in men the deep pelvis and the angulation as the ureter crosses the iliac artery make semirigid ureteroscopy more challenging and potentially dangerous. Attempting to force the semirigid ureteroscope past the iliac vessels may result in flap creation or ureteral perforation. In addition, pulsations from the iliac artery can cause inadvertent injuries during lithotripsy. Use of flexible ureteroscopy will decrease the risk of perforation in this region. Cases of “scabbard”-type ureteral avulsion have been reported when semirigid ureteroscopes have been used in tight ureters [42]. This type of avulsion occurs when the ureter is completely transected between two points, and is removed intact with the ureteroscope. Blind basket extraction in the ureter should be avoided, as it has been linked with cases of ureteral entrapment and avulsion [43].

When performing laser lithotripsy, one should avoid firing directly adjacent to the mucosa, utilize the lowest possible power settings that will achieve efficient fragmentation, and use caution when advancing the ureteroscope and fiber. If a significant perforation occurs, it is prudent to terminate the procedure immediately and leave a double-J stent to prevent submucosal stone fragment migration or enlargement of the injury. It is uncertain whether routine stenting reduces the ureteral stricture rate following uncomplicated ureteroscopy [14, 44, 45]. However, stent placement following ureteroscopy complicated by residual fragments, a urothelial flap, use of a ureteral access sheath, or a long-term stone may minimize the risk of subsequent stricture [46].

Any patients undergoing intact stone extraction who have residual pain or dilation on renal ultrasound should be evaluated with a CT urogram to evaluate for stricture [17].

## Management of mid-ureteral stricture disease

There are many options for the treatment of a mid-ureteral stricture including observation, endoscopic approaches (stenting, balloon dilation, and endoscopic incisional procedures), and more complicated open and minimally invasive reconstructive approaches (uretero-ureterostomy, ureteroneocystostomy with psoas hitch, Boari flap, transureteroureterostomy, and ileal ureter).

The least invasive option for the management of a mid-ureteral stricture is serial observation. Ureteral strictures that are not accompanied by pain and are not resulting in urinary tract infections, stone formation from urinary stasis, or renal deterioration on nuclear renography may be closely monitored to ensure progression of the disease does not occur [47]. However, poor follow-up may jeopardize renal function and the decision for observation must consider many subtle factors. For example, if diuretic renography shows obstruction in an asymptomatic patient but the function is preserved, the surgeon may choose observation. In contrast the surgeon may intervene in a symptomatic patient with a borderline T½ on diuretic renography, and decreasing function. All treatments should be embarked upon with restraint, after extensive counseling including all the options and following a carefully documented and detailed informed consent in order to avoid medicolegal complications.

Once the surgeon decides to intervene, the next decision is the optimal timing for the operation. In the 13–66% of patients presenting with intraoperative ureteral injury the treatment should be embarked upon immediately. In patients who are medically unstable or with complications following their ureteral injury, a period of 6–12 weeks with a nephrostomy tube or stent to allow inflammation to resolve is reasonable [48].

## Retrograde and antegrade stenting

Immediate temporary renal decompression can be accomplished in either an antegrade or retrograde fashion and the approach of choice may vary depending upon the clinical presentation. In patients presenting with acute hydronephrosis, refractory pain, or infection the initial evaluation and management is cystoscopy, retrograde pyelography, and ureteral stent placement. Stent placement bypasses the obstruction while preserving renal function and is also sometimes therapeutic. Antegrade or retrograde stenting has been shown to durably resolve ureteral strictures occurring in the transplant setting in up to 75% of cases [49]. Similarly, stenting of short-segment strictures due to irritation, edema, or inflammation (i.e. tuberculosis) while the underlying cause is corrected may resolve strictures in 49% of patients [50]. The limitations of retrograde stenting include discomfort, migration, infection, decreased effectiveness with extrinsic compression, and encrustation [51, 52]. Although changing stents every 3 months avoids encrustation, it is a less desirable long-term management strategy. Newer metallic and coiled wire stent designs have attempted to improve drainage with extrinsic compression with a 65% success rate at a 5 month mean follow-up [53, 54].

Retrograde stenting (double-J) has the advantage of being completely intracorporeal, while a nephrostomy tube has both an intracorporeal and an external component, making the nephrostomy more prone to inadvertent dislodgement. Another advantage of a retrograde ureteral stent is that the strictured lumen is stented open to prevent a dry ureter. In contrast the nephrostomy has the advantage of bypassing virtually any downstream obstruction and can allow for antegrade studies or therapies. The nephrostomy tube, however, by diverting the urine, may convert a partial to a complete ureteral obstruction due to a dry ureter.

Song et al. reviewed retrograde stenting in a series of patients with gynecologic malignancy and found an initial 81% success rate. However, 37% eventually received nephrostomy drainage at a mean 9.1 month follow-up [55]. Factors associated with stent failure on multivariate analysis were preoperative serum cystatin C levels >2.5 mg/l and stricture length longer than 3 cm [55]. Unlike previous studies [56], bladder invasion did not predict stent failure. Due to the high failure risk of an indwelling double-J stent, many authors advocate for nephrostomy drainage in cases with extrinsic compression. Park et al. [57] reviewed a small patient series with metastatic nongenitourinary cancer and determined that ureteral stenting failed in each case, but nephrostomy successfully relieved each obstruction. In a larger study by Ku et al. [58], patients with advanced malignancy and ureteral obstruction were approximately ten times more likely to fail indwelling ureteral compared with nephrostomy drainage.

One longer-term stent option to relieve ureteral obstruction is the thermoexpandable metallic stents that have been employed for the treatment of benign and malignant obstruction. In one of the largest series to date, Agrawal et al. described their long-term experience [59]. At a mean follow-up of 16 months, 14 of 55 patients (25%) required stent replacement, mostly due to stent migration, but only three patients had stricture progression that required a stent change.

When decompression is needed for a benign etiology (most commonly a stone), a randomized German study found superior outcomes across all variables in the nephrostomy group compared with the double-J stent group [60]. In another study, Pearle et al. randomized patients with septic obstructing stones to stent versus nephrostomy. In contrast to the prior study, there was no difference in efficacy or duration of analgesia, but retrograde stent placement was twice as costly [51]. Ultimately, the decision for nephrostomy or double-J stent depends upon a number of factors including the etiology, the likelihood of success with each procedure, the need for future therapies, the availability of the facilities and staff, and – perhaps most importantly – the patient's wishes.

## Balloon dilation

Initially developed for coronary arteries, balloon catheters have been shown to cause linear tears in the ureter, in a manner similar to an endoureterotomy [61, 62]. Both retrograde and antegrade balloon dilation are possible, but a retrograde approach is favored when the urethra, bladder, and ureter are in continuity. In this procedure a 5 or 6 Fr open-ended catheter is employed to perform a high-quality retrograde pyelography. Next, a flexible-tipped lubricious wire is passed via an open-ended catheter past the stricture and into the renal pelvis. The endhole catheter is then pushed above the stricture and the lubricious wire is converted to a standard or stiff guidewire. Alternatively, a single hybrid wire could be utilized. Next, the appropriate diameter (12–24 Fr) and length (4–10 cm) balloon catheter is inserted using fluoroscopic localization ensuring that the two radiopaque markers are straddling the stricture (Figures 52.5 and 52.6). Using half-strength contrast the balloon is inflated and held for 1–2 minutes. Optionally ureteroscopy can be performed to ensure complete dilation. A 6 Fr ureteral stent is routinely left in place for 4–6 weeks following the dilation (See Video 52.1). Reported short-term success rates of ureteral balloon dilation for short-length strictures are usually 48–55% [61, 63].

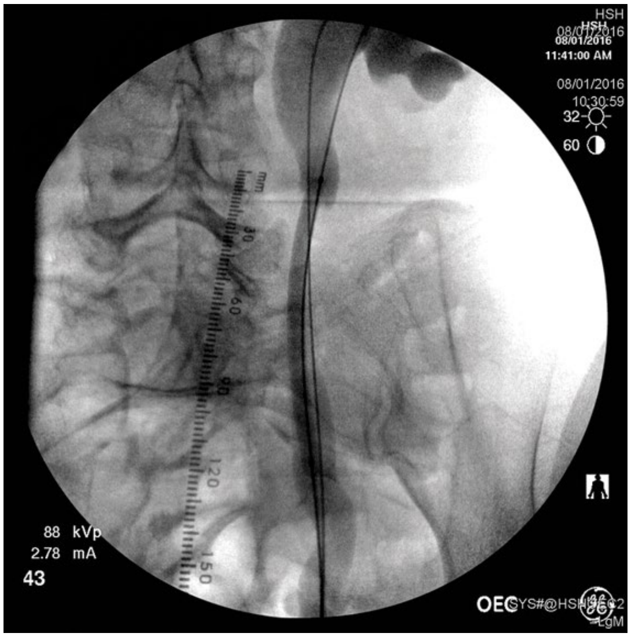

**Figure 52.5** An 18 Fr, 10 cm balloon is shown here dilating a proximal to mid-ureteral stricture.

## Endoureterotomy

Endoureterotomy is a relatively simple procedure where a full-thickness incision is made in the ureter to open a stricture [8]. It may be accomplished using different methods including a variety of electrified or nonelectrified cutting instruments and is frequently employed with balloon dilation. Since the earliest descriptions, the principles of endoureterotomy have changed little, except for the method of making the incision. The heterogeneity of studies (size and type of laser fiber, combination with balloon dilation, renal function, presence of crossing vessels, degree of hydronephrosis, and size and duration of stent) makes it difficult to compare studies

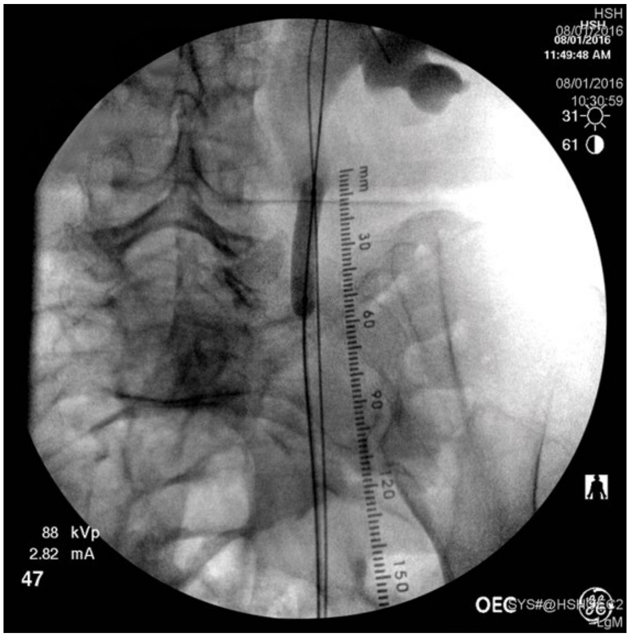

**Figure 52.6** A 24 Fr, 4 cm balloon is shown here dilating a proximal to mid-ureteral stricture.

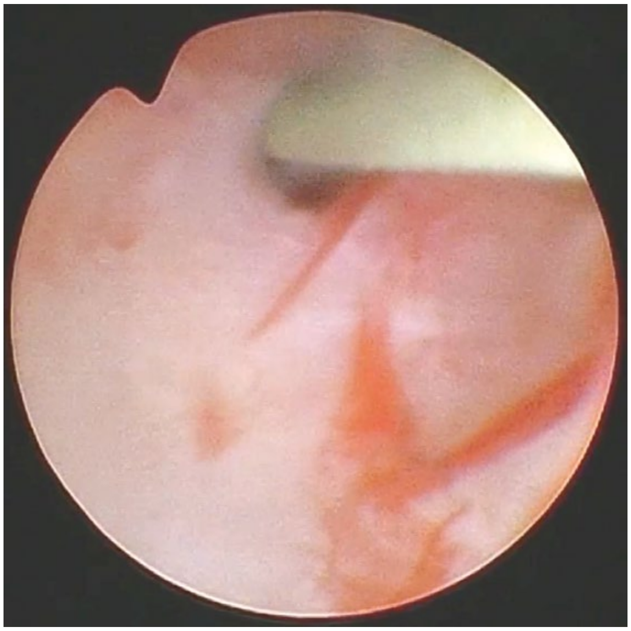

**Figure 52.7** Endoscopic view of a very narrow mid-ureteral stricture, with a safety wire passing through the stricture.

or identify a gold-standard technique for the performance of endoureterotomy.

The first step of endoureterotomy is to perform a retrograde pyelogram to delineate the stricture. Next a safety wire is placed across the stricture and a ureteroscope is used to evaluate the stricture site to exclude neoplasm or submucosal stone (Figure 52.7). If electrical energy is to be used an insulated wire should be employed. Next, a balloon catheter is used to dilate the stricture. Following this, a full-thickness incision of the ureteral stricture is created, directed away from the blood supply and extending 5–10 mm above and below the stricture. Currently, the most widely used and best-described instrument for incision is the holmium laser due to its shallow tissue penetration (<0.5 mm), excellent tissue vaporization, and coagulation properties [64]. Symptomatic patients have improved outcomes presumably because the stricture was not as long-standing, as well as those with a history of stone passage managed conservatively or with shock-wave lithotripsy [7]. Poor prognostic factors include poor renal function, presence of associated or crossing vessels, severe hydronephrosis, ischemic strictures, strictures >2 cm, and stricture due to endometriosis [65, 66]. Despite these limitations, the European Association of Urology state in the Laser guidelines that “Retrograde endoureterotomy is considered a first-line treatment option for ureteral strictures,” with a Grade C recommendation [67]. Most endoureterotomy failures occur 3–9 months after the procedure [68, 69], although some failures occur as late as 18 months after endoureterotomy [70]. This underscores the need for extended surveillance in all patients undergoing endoscopic treatment of ureteral strictures.

A special subtype of endoureterotomy is the hot-wire balloon (Acucise™) endopyelotomy [71]. This device was not frequently used for mid-ureteral strictures due to the risk of iliac artery injury if the balloon was not positioned correctly [72]. Although initially very popular, this technique has fallen out of favor due to difficulty controlling the cutting action, the risk of hemorrhage, and the much higher success rates seen with techniques employing direct vision and laparoscopic and robotic procedures [73].

## Rendezvous procedures

One dreaded potential iatrogenic complication is complete ureteral transection. This type of injury, when not detected intraoperatively, can lead to sepsis and the potential for renal loss. Diagnostic imaging will demonstrate no ureteral continuity (Figure 52.8 and Video 52.2). These injuries, when occurring in the mid ureter, are best treated by a reconstructive procedure like a Boari flap or psoas hitch since a blind puncture or cut outside the mid ureter may result in iliac injury. If there are contraindications to such techniques and the length of the stricture is less than 3 cm, one endoscopic approach that may be attempted is the “rendezvous” technique or endoscopic realignment. This technique involves feeding a wire antegrade into the retroperitoneum, then

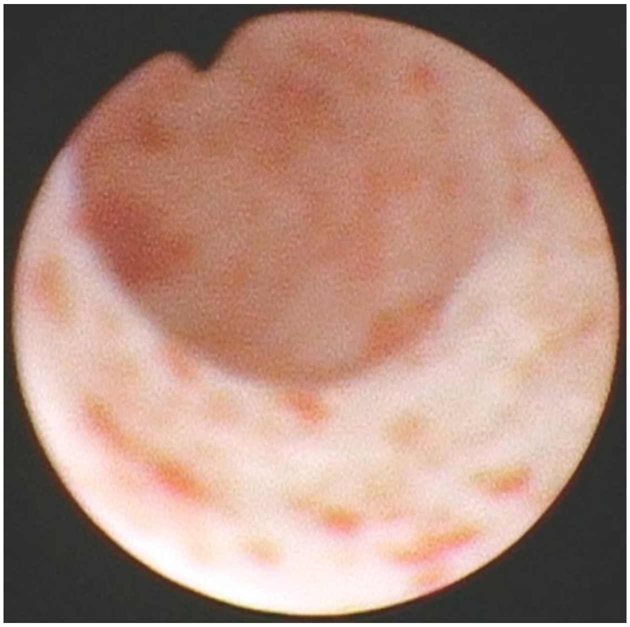

**Figure 52.8** Endoscopic view of a completely obliterated ureter.

grasping this wire with a semirigid ureteroscope from below to establish through-and-through access [74]. Alternatively use of a flexible ureteroscope from above and a semirigid ureteroscope from below provides the surgeon with greater control [75]. Using the latter technique Liu et al. achieved a 75% success rate at a mean of 21.5 months of follow-up. Tsai et al. achieved 100% success in 10 patients treated using this technique at a mean of 16 months of follow-up [76].

## Laparoscopic and robotic approaches

While more invasive than endoscopy, laparoscopic and robotic approaches have the advantage of removing the diseased ischemic tissue and creating a widely spatulated, tension-free mucosa-to-mucosa seal of the urothelium. In the mid ureter a laparoscopic or robotic ureteroureterostomy may be performed. The patient is positioned in a dorsal lithotomy position with moderate to steep Trendelenburg. Next, the ureter is mobilized above and below the stricture, and the pathologic segment is excised and sent for pathologic analysis. The ureter is then spatulated at both ends for a distance of at least 5–15 mm. The posterior anastomosis is performed using a 4-0 Vicryl suture, in either a running or interrupted fashion. Once the posterior portion is complete, a double pigtail stent is inserted across the repair, and the anastomosis is then completed. A drain is left postoperatively and the stent is left indwelling for 6 weeks [77].

Buffi et al. reported their experience with five lumbar and iliac ureteral strictures ranging from 5 to 30 mm long that were treated with a robot-assisted laparoscopic approach [78]. In all cases intraoperative flexible ureteroscopy was used to identify the stricture margins and there were no recurrences. Complete mobilization of the kidney can be performed if necessary to obtain additional length for the anastomosis. Overall, outcomes for laparoscopic and robotic ureteroureterostomy are good, although sample sizes in the majority of studies are small.

Mid-ureteral strictures longer than 3 cm may be treated with a high psoas hitch or Boari flap or more traditional approaches including an ileal ureter, autotransplantation, and transureteroureterostomy. The steps of a robotic ureteral reimplant for a stricture at the junction of the mid and distal ureter are demonstrated in Video 52.3.

When faced with longer-length strictures, excisional techniques are insufficient. Traditionally, long ureteral strictures have been treated by Boari flap, ileal ureter substitution, or autotransplantation. Each of these techniques have been reported using a robotic approach and for more details of these surgeries we refer the reader to Chapter 103. One group has looked at reducing the invasiveness of repairing long-length ureteral strictures by applying the buccal mucosal graft used in urethral reconstruction [79]. The authors noted a 100% success rate in three patients at a median 15-month follow-up. Other groups have experimented with different types of grafts, including lingual mucosa grafts and tubularized peritoneal flaps with varying success [80, 81]. Duty et al. reported on the use of appendix as an onlay flap for laparoscopic reconstruction of proximal and mid-ureteral strictures [82]. This approach has some drawbacks compared to the buccal mucosal graft as it enters the digestive tract, and two out of six patients required reoperation, including one nephroureterectomy. Laparoscopic ileal ureter has been described but should not be required for most mid-ureteral strictures [83].

In this chapter we have discussed the presentation, diagnosis, prevention, endoscopic incisional and laparoscopic and robotic excisional techniques for management of mid-ureteral strictures. Endoscopic management offers a minimally invasive solution to about half of patients presenting with mid-ureteral strictures. Following appropriate patient counseling it is reasonable to offer one or two trials of endoscopic management in short-length strictures (<2 cm), as long as split function is above 25% and other factors are favorable. However, patients with long-length strictures, ischemic strictures, or stricture due to extrinsic compression should probably proceed directly to excisional laparoscopic or robotic excisional techniques due to their higher success rates.

## Definition

A stricture is a short or long narrowing of the ureteral lumen which leads to functional changes causing decreased or complete interruption of urinary flow distally into the bladder or urinary reservoir. Obstruction can be mechanical, with altered anatomy, or functional, with impaired peristalsis without a true narrowing. A narrow lumen at the vesical or pelvic junction is sometimes called stenosis. Strictures of the ureter can be acute, such as postsurgical cases and ischemia, or chronic, as in postradiation therapy. Some varieties of stricture are congenital, with altered histology. The treatment options are influenced by a variety of factors but are often dependent on cause and the patient's comorbidities and preferences.

## Regional, histological, vascular, and endoscopic anatomy

Knowledge and understanding of ureteral anatomy is an absolute necessity for management of all ureteral diseases and prevention of iatrogenic injuries.

### Regional anatomy

The adult ureter ranges from 22 to 30 cm in length and is 6.5–7 cm in neonates [1]. On radiographs, the ureter may be divided into thirds: the upper third is from the ureteropelvic junction (UPJ) coinciding with L2 vertebrae to the brim of the sacrum; the middle third is from the upper to the lower border of the sacrum; and the segment from the lower border of the sacrum to the ureterovesical junction(UVJ) is called lower or distal ureter. The upper ureter is called the lumbar or abdominal ureter and the distal segment is referred to as the pelvic ureter. The intramural ureter is about 1.2–2.5 cm in adults and 0.5–0.8 cm in neonates. The UPJ and UVJ or ureteral orifice have their own characteristics and configurations from normal to abnormal shapes and locations and their own specific procedures. In a contracted bladder the ureteral orifices are 2.5 cm apart, which can increase to 5 cm when distended.

The renal pelvis typically lies posterior to the duodenum on the right and the jejunum on the left. The ureter begins posterior to the renal artery and vein then descends in the retroperitoneum, moving anteriorly over the psoas muscle and passing under the gonadal vein at the level of the inferior pole of the kidney. It travels on the pelvic wall and at the ischial spine enters the pelvis, turns anteromedially, medially crossing the iliac vessels. The two ureters are 5 cm apart with physiologic narrowing at this point. The ureters then diverge laterally at the same course in both sexes with gender-specific differences. In men the ureter travels down medially and lies in the sacrogenital fold; it is dorsal to the vas deferens that crosses it medially. In women, the ureter is initially posterior to the ovary, passes posterior to the round (ureterosacral) ligament with the uterine artery travelling medially. It is about 2 cm lateral to the uterine cervix and courses anterior to the vagina's lateral border. In both men and women the ureters travel past the dorsal aspect of the medial umbilical ligament and superior vesical artery. The transition of ureter into the bladder causes the lower physiologic narrowing. The three narrow points of the ureter are the UPJ, the crossing point over the iliac vessels, and the UVJ, which is the narrowest. The typical S-shaped curvatures of the ureter can be appreciated on anteroposterior and cross-table views of the ureter [2]. See Figure 53.1.

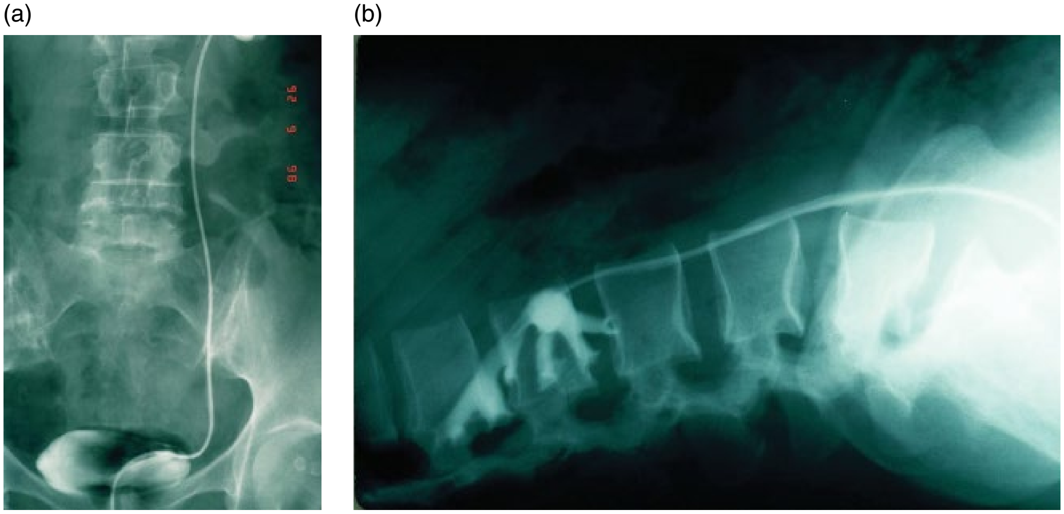

**Figure 53.1** (a) Anteroposterior view of the abdomen with a catheter in the left ureter showing the S-shaped (right–left, up–down) curvatures of the ureter. In older women the ureter dips down before turning up cephalad due to bladder or pelvic prolapse whereas in older men the so called J-hooking is due to elevation of the intramural ureter secondary to prostatic growth. (b) A cross-table view of the ureter with the patient in supine position shows the anteroposterior curvatures of the ureter.

## Vascular anatomy

The ureters are have multiple arterial sources as they travel caudally. The proximal ureter is essentially supplied by the lower pole renal arterial branches anteriorly. This section, referred to as the golden triangle, has significant value during donor nephrectomies, to preserve the only arterial supply to the ureter. The gonadal artery and the aorta also contribute to the upper ureter. The gonadal artery and common iliac artery provide the blood supply to the middle third of the ureter. The spermatic artery supplies up to 10% of ureteral blood supply. The distal ureter is supplied by branches of the common iliac and internal iliac arteries, superior vesical artery, and the uterine and vaginal arteries in women and inferior vesical artery in men.

Ureteral arterial vessels travel longitudinally within its adventitia and create a branched network, allowing for mobilization without risking its blood supply. The venous drainage is paired with the arteries and drains to the renal, gonadal, and internal iliac veins and vesical venous plexus. Knowledge of this vascular supply is crucial in ureteral surgery, because a devascularized ureter is subject to complications of stricture and leakage.

Lymphatic drainage of the upper ureter is into the lumbar and para-aortic nodes on the left, and the paracaval and interaortocaval nodes on the right. Lymphatics of the middle ureter drain to the common and internal iliac nodes, while those of the pelvic ureter drain to the internal iliac and vesical nodes. See Figure 53.2. Ureters have a richly innervated plexus arising from T12–L2 segments of the spinal cord with corresponding dermatome referral [3]. The kidney's sympathetic innervation is from T8 to L1 and travels along arterial branches, causing vasoconstriction, and the parasympathetic fibers arise from the vagus nerve, causing vasodilation. The loss of renal and especially ureteral innervation has significant implication in ureteral strictures. This is seen in transplanted kidneys, patients who have undergone extensive manipulation of the ureter, and procedures such as Boari flap or reimplantation. The lack of ureteral innervation can mask the clinical presentation.

## Histologic anatomy

In an adult the thickness of a nondilated normal ureter and peri-ureteral adventitia is about 3 mm. In a review of 212 unobstructed ureters on computed tomography (CT) scan 96% of the ureters had a diameter of 3 mm or less [4]. The ureter is lined with transitional cell epithelium, which consists of a short basal layer, one or more layers of columnar cells, and, most apically, umbrella cells. The umbrella cells are specialized to survive bathing in hypertonic urine and to stretch with distention of the lumen. Folds of mucosa help to protect against reflux of urine when the bladder is full [5].

Underneath the epithelial layer is a thick, fibroelastic matrix, known as the lamina propria. It is a packed layer of cells that allows for stretching of the ureteral wall when obstructed. The ureter has no mucosal or submucosal glands, and no submucosa. The thickest layer of the ureter is the muscularis, which is a layer of smooth muscle outside the lamina propria: the upper two-thirds have two layers of muscle: the inner arranged longitudinally and outer arranged circularly. The muscular layers contribute to peristalsis. The lower third has a thicker

**Figure 53.2** (a) Vascular supply of the ureter. Note the longitudinal descending pattern of the upper ureteral blood supply, and the medial and lateral vascular supply of the mid and distal ureter [7]. (b) Paraureteral structures. This diagram illustrates the ureteral anatomy, vascular supply, and adjacent organs to help create a virtual anatomy in the operator's mind. A & V, artery and vein.

urothelium and three layers of muscle: the inner longitudinal, middle circular, and outer longitudinal. See Figure 53.3. The distal end of the ureteral musculature flattens and rolls under to allow the lumen to migrate to the vesical mucosal surface. In the intramural section the muscle layering is lost and all fascicles become oriented longitudinally and fan out to form the trigone. Within the bladder wall the ureter is loose (Waldeyer's separation) [6]. This anatomic description explains why, during endoscopic meatatomy in the 12 o'clock position, muscular layers are rarely noted [7]. The outer adventitial layer has fibroelastic connective tissue. This layer harbors the blood vessels, lymphatics, and nerves. This histological structure along with the richer vascular supply explain why the distal ureter is more resilient and forgiving as compared to the upper ureter during endoscopy and after iatrogenic injuries. The ureteral lumen is not actually a circle but folded epithelium that is stellate in form, mostly with five or six points. The points of the stars are the last to disappear with ureteral dilation and with further dilation the ureteral lumen takes a square shape and eventually a circle, allowing it to distend up to 17 times when obstructed [8].

The proximal part of the ureter is prone to higher shear stress during peristalsis compared to the middle and distal parts [9]. Disruption of the ureteral muscle layers during mechanical dilation of the ureter in conjunction with ureteroscopy is one of the main causes of subsequent strictures [10]. Pelvic surgery, skeletonization, and radiation can result in significant vascular compromise of the distal ureter, resulting in secondary strictures. The pattern of ureteral stricture and degree of dilation partly depend on this histological structure. The upper ureter, with fewer muscle layers and loose surroundings, allows for significant dilation which functions as a reservoir in cases of severe obstruction and allows for tortuosity to accommodate urine volume and keep the renal pelvic pressure low. The loose structure, on the other hand, makes this part

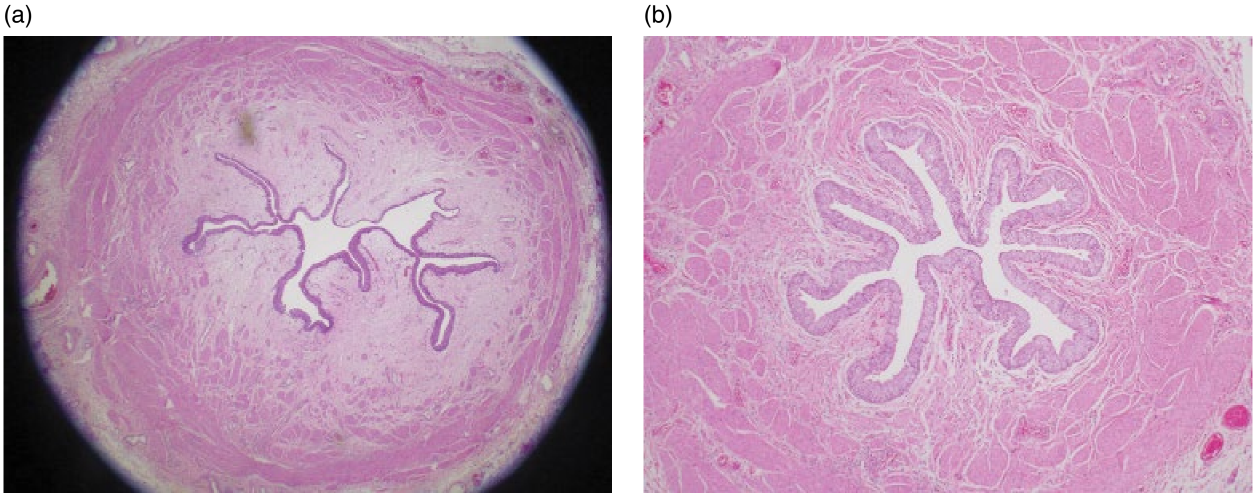

**Figure 53.3** Histology of the ureter. (a) Upper ureter: note the stellate appearance of the lumen. There are only two muscular layers in this segment; from the inside out: urothelial mucosal folds, lamina propria, longitudinal muscle, outer circular muscle, and adventia. (b) Cross section of the lower ureter showing increased thickness of the urothelium and additional muscular layer.

weaker and more prone to injuries. The majority of ureteral avulsions occur in this segment due to the lesser musculature and no paraureteral support. In the lower ureter the degree of dilation is less due to thicker muscle layers and also rather tighter space. In this segment, strictures from iatrogenic injuries and impacted stones are usually short in length with normal ureter below and above, except for cases of hydronephrosis. In cases of pelvic surgery, radiation, malignancies, and fibrosis the ureter is restricted externally and the obstructed segment is long with the appearance of an irregular piece of string. The ureter additionally loses its mobility and appears fixed, even with placement of a catheter; this is in contrast to a normal ureter that takes the shape of an open-ended catheter or balloon and looks straight [10–12].

## Virtual anatomy

Virtual endoscopic anatomy can be defined as a three-dimensional reconstruction of the ureter in the mind of the operator. This reconstruction includes what is visualized endoscopically to the regional/vascular/histological information described earlier. The key additional information relates to paraureteral structures. The surgeon can make the best judgment in selecting the procedure and the extent of the intervention, regardless of the nature of the procedure, to achieve the best and safest outcome. There are three layers of information: (i) visible intraluminal findings, (ii) visible and invisible ureteral wall histovascular anatomy, and (iii) invisible regional and paraureteral structures. The combination of these factors creates a three-dimensional virtual anatomy in the operator's mind. Figure 53.4 elaborates some of the details and recommendations for safe incisional sites.

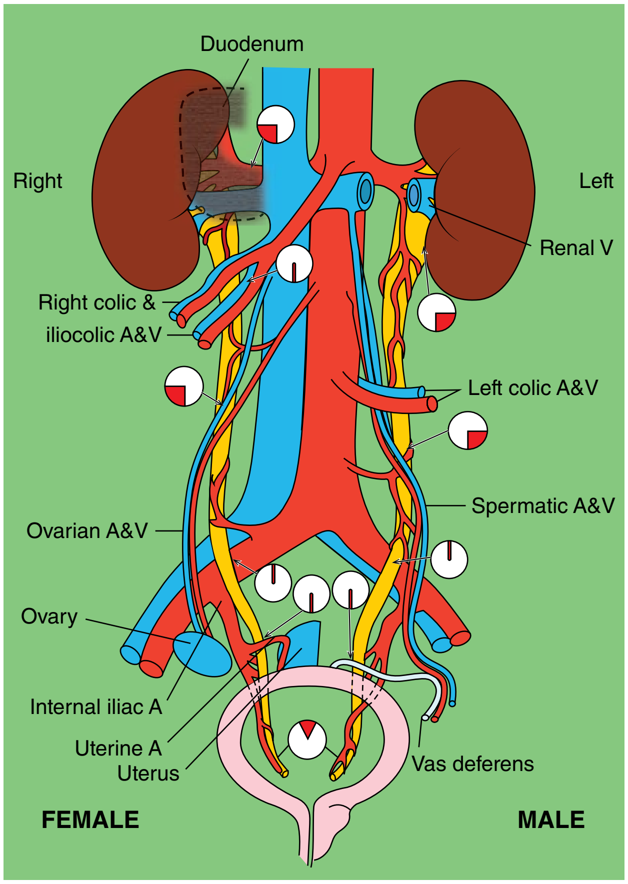

**Figure 53.4** Ureteral and paraureteral structures with the recommended sites of incision.

### Altered anatomy

Normal anatomy of the distal ureter can be altered by past surgical procedures, which renders the management of strictures more challenging for the surgeon. Recommendations to overcome them are described here.

## Ureteral reimplantation

Ureteral reimplantation is performed using a variety of techniques and in the event of subsequent obstruction it can potentially be difficult to access the relocated neo-orifice.

- **Cohen cross trigonal reimplantation**: this is carried out by advancing the intramural ureter by creating a new submucosal tunnel cross-trigonally. These ureters can be quite difficult. If rigid and flexible endoscopy in combination with angled catheters fails to negotiate the neo-orifice, antegrade insertion of a guidewire followed by either antegrade or retrograde dilation, preferably with a low-profile balloon, is the next step [13, 14].
- **Gil-Vernet trigonoplasty**: in this technique the area in front of the ureteral meatus is plicated, thus increasing the additional length to overcome the reflux. Access to this ureter may be slightly difficult; an angle-tipped catheter or a flexible cystoscope can overcome this problem [15].
- **Politano-Leadbetter**: this was the originally described technique of reimplantation for refluxing ureters. The ureter is detached and reimplanted posterolaterally into the bladder in an up–down fashion. Obstructions are usually due to poor location of the implant site causing kinking rather than luminal blockage. Access for true strictures is usually easy in an underdistended bladder [16].
- **Paquin technique**: this reimplantation technique is rarely used by pediatric urologists. This requires lengthening the intramural and inverted meatoplasty. Direct visualization of the lumen with a small scope or ureteroscope helps initial placement of the wire [17].
- **Lich-Gregoire technique**: in this technique an extended tunnel is created extravesically and the meatal anatomy is unchanged, so the ensuing stricture is mostly due to a very tight distal ureter and access to the ureter is usually easy [18, 19].
- **Modified Lich-Gregoire technique**: this technique is commonly used in transplantation where the tunnel is created extravesically with two variations for ureterovesical anastomosis. First is the fish-eye technique and is typically located anterolaterally in the bladder. Access to this neo-orifice is usually not very difficult. The cause of the stricture is either poor blood supply of a compromised ureter or a tight closure of the meatus and distal tunnel. Second, some transplant surgeons use the spatulated inverted distal ureter technique anchored to the bladder, creating a nipple. This technique has a low reflux incidence. In cases of true stricture the retrograde access can be very difficult. The patient may need a nephrostomy tube and antegrade guidewire placement. After dilation, an endoureterotomy can be done in a retrograde fashion. Double pediatric reimplants with a single tunnel create additional difficulties due to side-by-side ureters in a narrow tunnel and stenting of one ureter may cause mechanical obstruction of the second ureter. It may be necessary to stent both ureters with a smaller stent: 4.8–5 Fr. Another cause of ureteral obstruction of a short transplant ureter is rotation of a transplant kidney and angulation of the ureter at the UPJ or lower. Some of these patients require long-term stenting to stabilize the shape and curves of the ureter. Natives to transplant ureteroureterostomy has similar problems at times. See Figure 53.5.
- **Glenn-Anderson-O'Donnell-Puri technique**: this advances the orifice towards the bladder neck and is usually easy to access and dilate. Caution needs to be exercised if the opening is very close to the bladder neck in women. The O'Donnell technique is a submucosal injection of bulking agents without changing the anatomy. It is usually used for vesicoureteral reflux [20, 21].
- **Psoas hitch**: this is an additional maneuver to compensate for a shortened ureter. The implanted neo-orifice may be slightly higher or lateral depending on the technique and if it strictures it can usually be accessed in a retrograde fashion.

## Boari flap

Since the ureteral anastomosis is at the end of a tubularized flap it is rather far from the bladder neck, especially in male patients with an enlarged prostate. A flexible cystoscope or a semirigid ureteroscope is useful for reaching the obstructed anastomotic site for initial wire placement.

## Neobladder

Urinary reservoirs present special problems in cases of stricture and obstruction of the implanted ureter. Some of the implants form a chimney structure and some have a short tunnel with direct anastomosis to the bowel mucosa or are inverted with nipple formation.

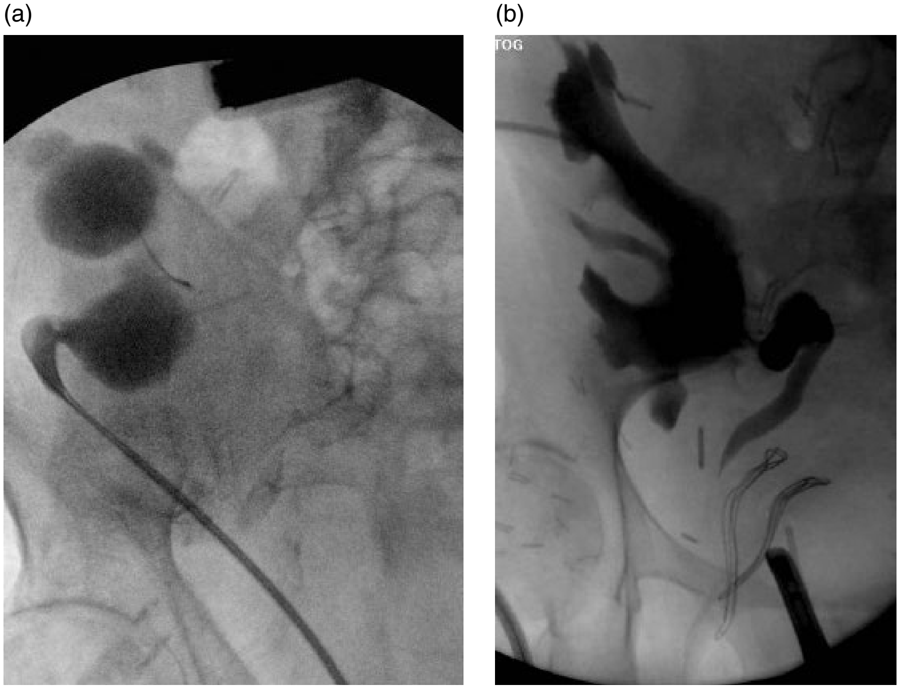

**Figure 53.5** (a) A rotated right lower quadrant transplant kidney (the renal pelvis faces laterally) with ureteral obstruction. (b) A right ureteroureterostomy with stricture and angulation.

The disadvantage is a lack of normal bladder boundaries to help identify the implant site.

## Extirpative and reconstructive pelvic surgery

Radical prostatectomy, abdominoperineal resection, hystero-oophorectomy, bladder neck reconstruction, pelvic floor reconstruction, and a variety of bladder neck suspension procedures can, at times, contribute to the development of ureteral strictures. This can be due to anatomic or histological causes such as dissection and cauterization.

Some pelvic reconstructive procedures can cause angulation and distortion of the natural course of the intramural ureter as well. The best approach is careful inspection of the area and placement of a guidewire to be followed with either mechanical dilation or incision in long and dense strictures. Posthysterectomy distal ureteral obstructions are mostly above the intramural section and are mechanical or ischemic due to thermal injury to the vasculature and the tissue directly. In such cases the lumen is not actually compromised. An initially valuable instrument is a semirigid ureteroscope, allowing direct access to the orifice. This allows the wire to be inserted, with the scope keeping the wire from curling (bellying) outward. The use of hydrophilic guidewires such as Sensor, Roadrunner, or Glidewire are additionally advantageous. After negotiating and stabilizing the access we generally change the Glidewire into a more stable wire such as the Amplatz superstiff wire or a Sensor wire. In cases of obstruction above the orifice a mini semirigid ureteroscope (6 Fr) is advanced to the area of narrowing to allow for direct and atraumatic insertion of the wire through the compromised lumen without creating any false passages. This can later be incised using a cold-knife endoureterotome without any thermal injury. See Figure 53.6 and Video 53.1.

## Pelvic malignancies

Bulky pelvic malignancies create a different type of challenge. A common example is a female patient with bulky uterine mass, postradiation. In these cases obstruction of the distal ureter is a combination of mechanical changes due to anteromedial dislocation and secondary postsurgical/postradiation histological changes. The stenotic ureteral orifice is located centrally on a mound facing the lateral aspect of the bladder: the mirror image of the natural orientation. The ureter then takes a medial and a sharp lateral curve towards the renal pelvis depending on the degree of the ureteral tortuosity. The use of Kumpe, Cobra, and other types of angiographic catheter

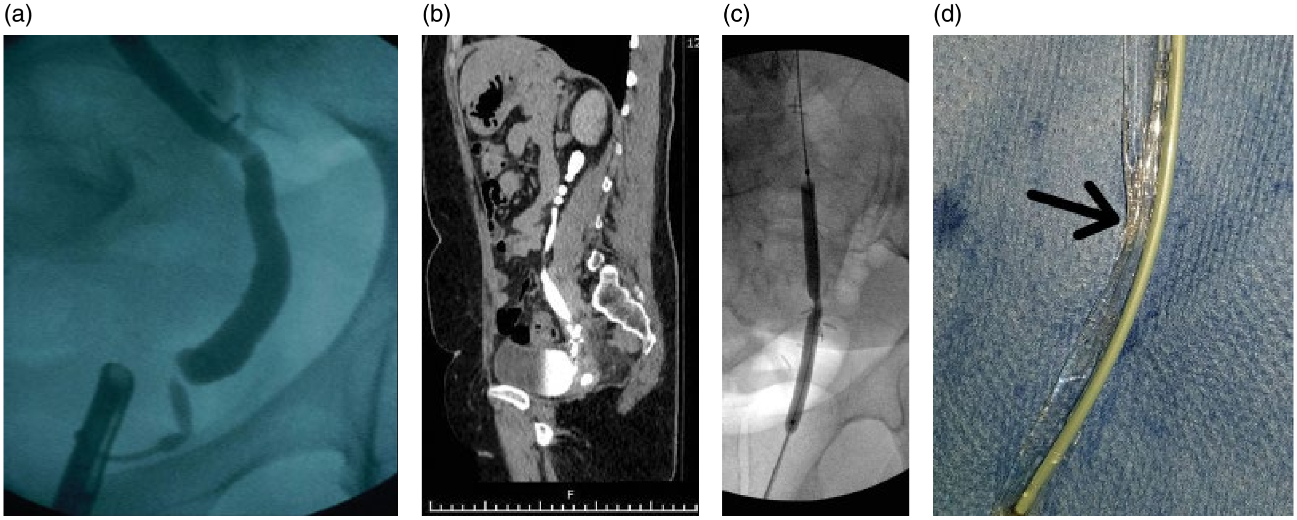

**Figure 53.6** (a) Retrograde pyelogram of a female in the immediate postoperative period after hysterectomy showing leftdistal stricture/obstruction secondary to suturing. The cold-knife incision intraluminally released the suture with no recurrence on follow-up. (b) CT urogram image of a female patient 5 weeks postradical hysterectomy and pelvic lymph node dissection with complaint of flank pain and urine leak from the vagina. (c) Radiographic appearance of resistance to balloon dilation with a ring effect (persistent waist). (d) Appearance of the balloon after removal showing persistence of waist: a sign that the stricture is not adequately dilated.

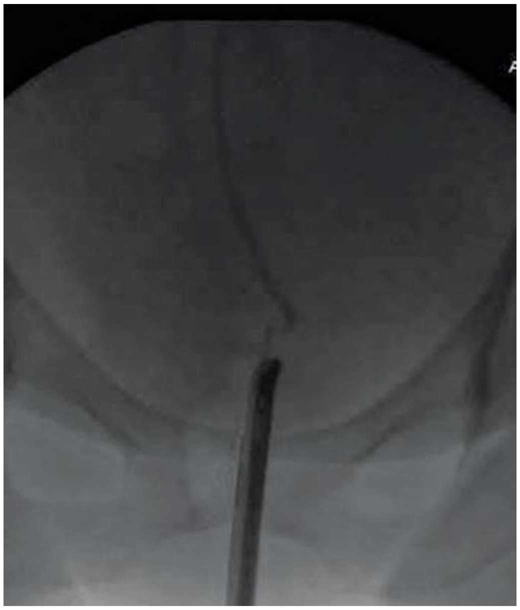

**Figure 53.7** Obstructed distal ureter due to bulky pelvic tumor. The orifice is medially and anteriorly displaced.

is very helpful to overcome these angulations and types of tortuosity [22]. See Figure 53.7.

## Instruments

A variety of instruments are used to manage ureteral strictures endoscopically or under fluoroscopy. Some are used by interventional radiologists in an antegrade fashion when urologists do not have enough expertise or, at times, desire to do the procedures. The majority of these can easily be used by urologists who have had adequate endourological training or exposure. The instruments used are from the urology and radiology armamentaria.

### Angled angiographic catheters

These catheters are used in parts of the ureter that are kinked or angulated. Intubate with a guidewire or Glidewire, rotated clockwise or counterclockwise while simultaneously advancing it. See Figure 53.8.

### Guidewires

There are multiple types of guidewire which are used in these procedures, with each specific guidewire designed for a certain purpose. The common types are stainless steel, PTF coated, stainless steel-coated with a hydrophilic tip (Sensor, Boston Scientific, Marlborough, MA, USA), all hydrophilic (Glidewire, Terumo, Somerset, NJ, USA; Roadrunner, Cook Medical, Bloomington, IN, USA), and coated rigid shaft with a floppy tip (Amplatz superstiff). They range in diameter (0.014–0.038 inches), length (140–150 cm), tip shape, and level of stiffness. The most common wires used in urology are 0.035 and 0.038 inches. The floppy soft tip varies from 3 to 5 cm depending on the product. Tip shape may be angled, straight, floppy, or J-shaped.

In general, the ideal endourologic guidewire should be sufficiently flexible and lubricated to negotiate a

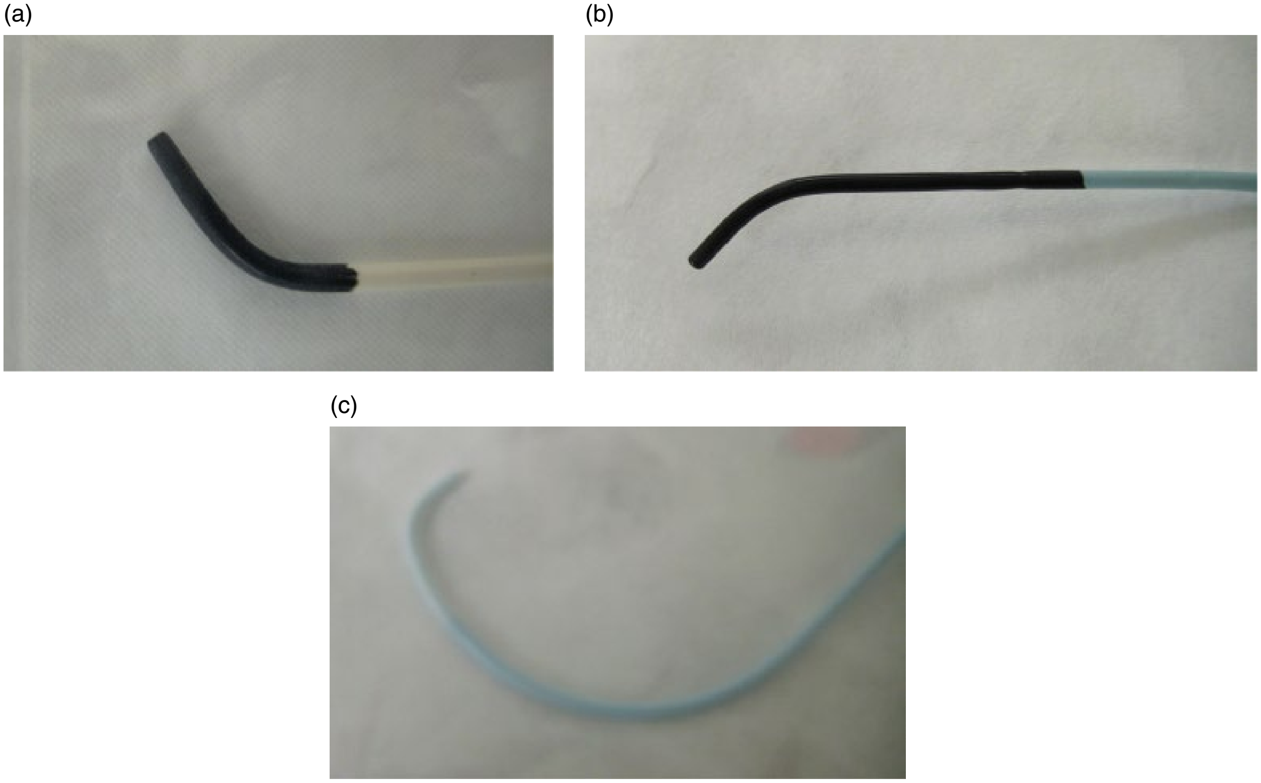

**Figure 53.8** Angle-tipped angiographic catheters for negotiating a stenotic orifice and tortuous ureter.

tortuous ureter and pass possible obstructions with adequate strength against bending for stability to pass the stent over.

If guidewires cannot pass the stricture, a hydrophilic guidewire (Glidewire) can be used bypass a strictured area. A disadvantage is that hydrophilic guidewires are very slippery and easily dislodge out of the ureter. An external device clipped to the end of the Glidewire makes it easier to handle and control [23].

## Meatotomy scissors

Meatotomy scissors, one of the oldest pieces of equipment in the urological armamentarium, is ideal for incising a stenotic ureteral orifice. The very first indication for meatotomy was for facilitating the passage of a stone through a small ureteral orifice. Endoscopic scissors are used to incise the orifice along its intramural course medially, This approach is taken because the distal ureter's blood supply enters it laterally, from the inferior vesical artery: 12 and 2 o'clock on the right and 10 and 12 o'clock on the left.

## Endoureterotomy scissors (Storz)

This is a type of single-action rigid or flexible scissors with the cutting edge facing outward when passed through a rigid ureteroscope. When the scissors are opened in the stenotic intraluminal portion and withdrawn, with proper orientation the dorsal aspect of the upper blade incises the ureteral stricture. This is called reverse cutting [24]. See Figure 53.9.

## Stricture knife (Cook Medical)

The stricture knife was also designed for semirigid ureteroscopes and is not commonly used. It includes a narrow-profile catheter with an inner scalpel which is advanced through the area of stricture and slowly withdrawn under direct vision to incise the stenotic area.

## Greenwald needle

This 3 Fr needle is inserted into the bed of a stricture to instill triamcinolone to decrease the rate of collagen production and thus decrease recurrence rate. Some studies have reported a 50% response rate at 5 year follow-up.

## Collin's knife-electrode

This 45° angled electrode is used to incise the intramural ureter and obstructed ureterocele using the standard transurethral resection set. If the opening of a ureterocele is accessible then a wide meatotomy can be performed.

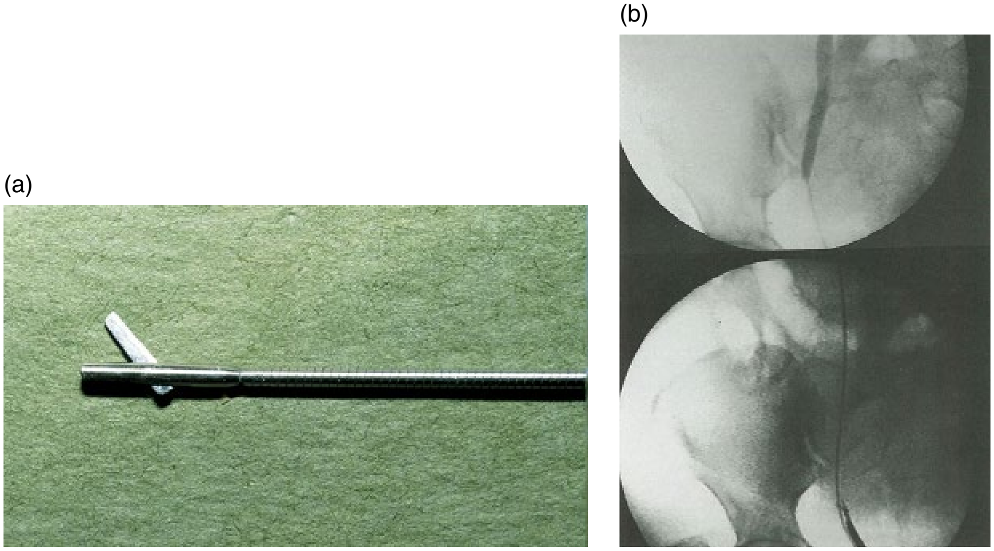

**Figure 53.9** (a) Close up of endoureterotomy scissors. The sharp dorsal aspect of this instrument is ideal for reverse cutting. (b) Radiographic appearance of endoureterotomy.

Most urologists recommend incising the base of the ureterocele horizontally at the medial aspect as this gives the best chance of avoiding reflux afterwards [25].

## Laser fiber

Neodymium (Nd):YAG and Ho:holmium lasers may be used with semirigid and flexible ureteroscopes to incise stenotic areas under vision. Both 200 and 365 μm fibers may be used depending what size ureteroscope is used. The 365 μm fiber fits the lumen of most semirigid ureteroscopes. The lowest possible energy must be used to minimize thermal injury. YAG should not be used primarily as it may cause necrosis.

## Angled Bugbee electrode (Greenwald)

This 3 Fr angled or straight electrode is used to incise a stricture using an electrical current. The downside is that the added electrical energy can damage an already compromised vascular supply.

## AQ Taper and Nottingham one-step dilators (Cook Medical/Boston Scientific)

These sequential or graduated fascial dilators (6–12 and 12–18 Fr) or a variation of Teflon dilators are advanced over a guidewire under fluoroscopic control to dilate a narrow segment of the distal ureter prior to ureteroscopy. This longitudinal force can result in tears and splitting of muscle layers that can potentially cause stricture formation (see Figure 53.10) [26].

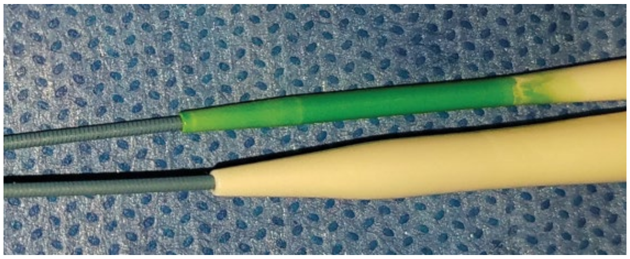

**Figure 53.10** Tapered 6–12 and 12–18 Fr fascial dilators. The tapered tip matches a 0.038 inch guidewire without any gap, avoiding tissue dragging and decreasing mucosal damage. The larger diameter of the dilator as compared to the smaller ureteral lumen still causes mucosal and muscular injuries.

## Bugbie dilators (Storz)

These stainless steel devices are available in single size or graduated size on a single shaft. Their purpose is for dilating stenotic distal ureters.

## Balloon dilators

Since the introduction of balloon dilators by Grüntzig in 1978, they have been used to dilate the ureter prior to ureteroscopy. Balloons are the most common form of stricture dilator. Dilated balloon outer diameters (OD) range from 15 to 24 Fr with marked lengths of 4–10 cm and tapered shoulders. The balloons have a set range of pressure tolerance and can rupture if overinflated. Use of a pressure gauge can avoid this problem. If a balloon is placed too close to a dense stricture it has a tendency to slide out of position. In narrow ureters it is often difficult to advance a balloon once it is inflated and deflated;

therefore, in long segments, it is best to advance the balloon to the proximal end and withdraw it segmentally. The balloon must be deflated completely, the syringe removed, and the valve open during withdrawal. This maneuver prevents the ureter from being dragged during withdrawal.

A balloon's maximum pressure tolerance is described in atmospheres (atm) or pounds per square inch (psi) and rarely in kilopascals (kPa), where 1 atm = 14.7 psi = 101.3 kPa. A simplified rounded formula is 1 atm = 15 psi = 100 kPa.

Uncontrolled overinflation of the ballon can result in rupture and possible disruption of the ureteral wall continuity. If a pressure gauge and Leveen (spiral cylinder)-type syringes are not available then smaller (2–5 ml) syringes can be used, but produce high pressures. A zero-tip balloon, which has no shoulder, can be used to dilate the point of obstruction before endoscopy.

Balloon dilation causes circumferential histological injury but is less traumatic than fascial dilators. In a study by Schwalb and Eshghi [10], mechanical dilation was found to cause more sites of immediate mucosal trauma. Six weeks later, mechanically dilated ureters showed extensive scarring and muscle loss. There was significantly less damage with balloon dilation and hydraulic dilation for ureteroscopy was atraumatic [10].

### Acucise endopyelotomy

The Acucise kit is used for fluoroscopic incision without endoscopy. A 10 Fr balloon, which helps define the area of stenosis, places the cutting wire against the tissue for direct incision. The inflated balloon (which may reach 24 Fr in OD) is left for 10 minutes after incision is made for tamponade. Placing the orientation of the cutting wire away from vessels and paraureteral vital structures is the key factor to avoid incising vital structures. The dilated balloon can create tense pressure and place the ureter directly against adjacent structures such as uterine, iliac gonadal, and lower pole vessels and once the electrical wire is activated it can potentially incise through the ureter and adjacent vessels. This instrument has been used in the treatment of UPJ obstruction as well as ureteral strictures [27–33].

### Endoureterotome (Wolf, Storz, Olympus)

A dedicated endoureterotome is most useful and yet is one of the most underused instruments in the ureteroscopic aramamentorium. There are three models of this rigid instrument with variations in their shape, length, and tip configuration – cutting cold knife, either straight (Storz) or half-moon-shaped (Wolf, Olympus) – which are described as follows.

#### Wolf endoureterotome

This is the most user-friendly of the three. It is a three-piece instrument and is part of the ureteroresectoscope set. The working element has a locking mechanism to hold the half-moon cutting knife in place. The rod lens is inserted through the element and into the sheath which is 41 cm long with an OD of 11 Fr. The rounded beak is at the top of the instrument. The cutting knife also has a hollow channel allowing a 0.025 inch wire which ensures that the blade follows the wire and remains intraluminal at all times. This instrument is also used for endopyelotomy.

#### Olympus endoureterotome

This device has similar elements to the Wolf but the length is 38 cm and the OD is 13 Fr. The beak is at the bottom. The advantage is that it has a larger half-moon cutting element that can slide over a 0.038 inch wire and is perfect for very distal strictures. The major disadvantage is the larger OD and so it is not ideal for higher lesions.

#### Storz endoureterotome

This instrument is actually a 36.6 cm long ureteroresectoscope with a similar type of working element. It has an OD of 11.5 Fr and an oval insulated tip. A straight or serrated knife is used for cutting. It is hard to advance this instrument to upper nondilated or tight ureters. It may be beneficial to initially stent the ureter to allow for passive dilation and decompression of the upper tract. See Figure 53.11.

## Stents

Stents vary in shape, size, design profile, and material and are almost always needed after any procedure associated with endoscopic or radiological treatment of ureteral stricture. Most stents are for general use while some are designed for stricture disease.

### Coating (antibiotic-eluting stents)

Antibiotic-coated stents have been tested on animals; rifampin-coated stents showed efficacy against *Enterococcus* infection. An *in vitro* study assessed the efficacy of a sustained-release varnish containing chlorhexidine against three common bacteria in the urinary tract (*Enterococcus*, *Escherichia*, *Pseudomonas*) and was shown to be effective against all three species. Triclosan-eluting ureteral stents changed every 3 months did not result in reduced infection rates in this chronically colonized group; however, the rate of symptoms and requirement for antibiotics were significantly lower [34–36].

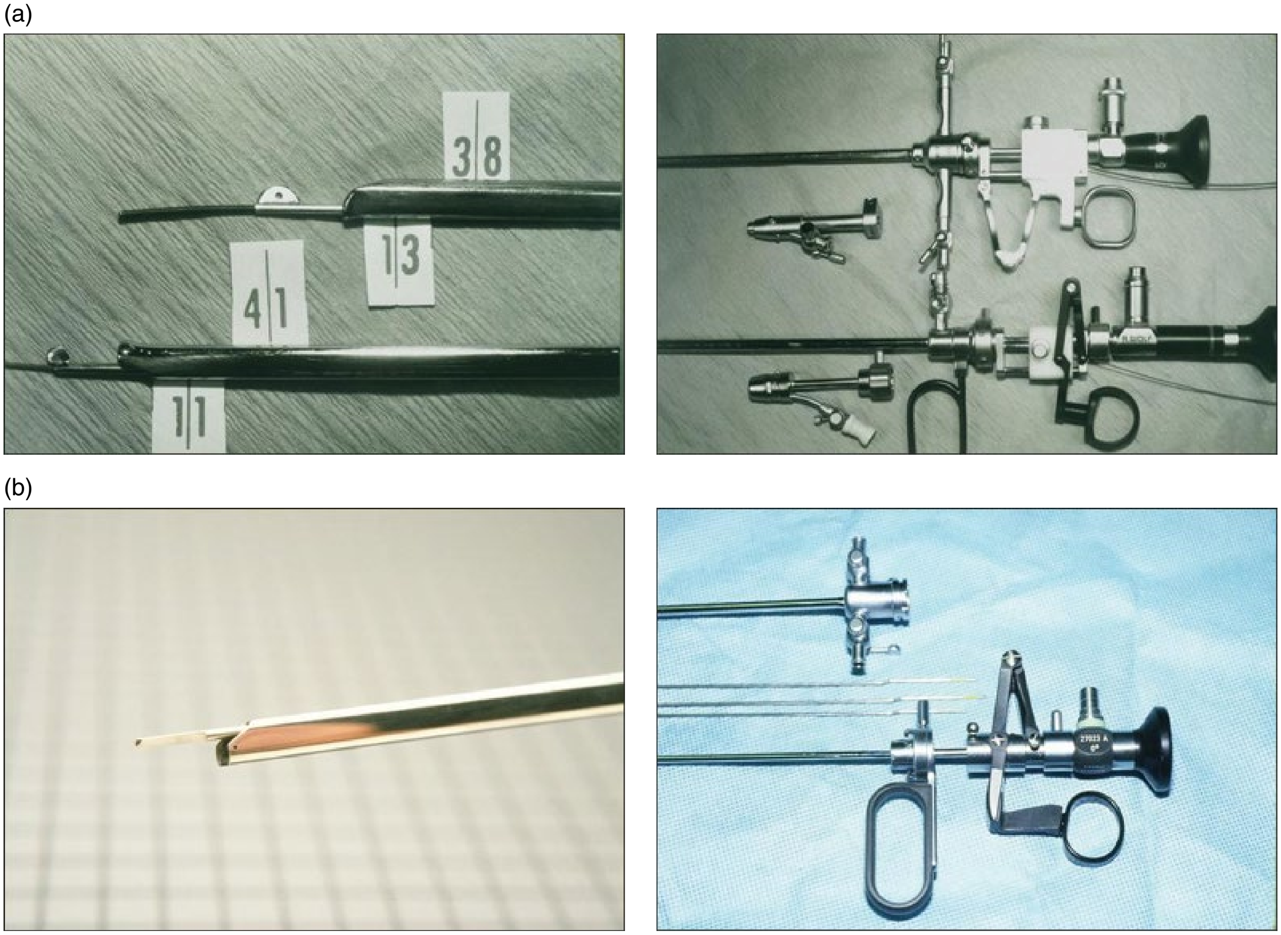

**Figure 53.11** (a) The Wolf and Olympus endoureterotome for cold knife incision with a half-moon guided knife. (b) The Storz endoureterotome with a straight knife.

In an animal study stents initially increased peristalsis but later reduced or stopped it. Stent material did not affect peristalsis but smaller stents caused less of an immediate effect on peristalsis than larger stents [37]. In another numeric analysis, a computational fluid dynamics simulation showed that curved stents with side holes provided better drainage compared to straight models [30].

- Regular double-pigtail stents: this type of stent, originally known and marketed as the J or double-J stent, had lesser proximal and distal curvatures compared to the double-pigtail stent with 360°. A large variety of polymers are used with an OD of 4.8–14 Fr at different lengths.
- Silicone stent (Cook Medical): this stent is made of pure silicone and is quite soft, resistant to encrustation, well tolerated, and recommended for long dwelling periods. This stent is ideal for cases of recurrent soft strictures or drainage problems.
- Endopyelotomy-endoureterotomy stents are used after the thus-named procedures, and are available in lengths of 22–30 cm and two different diameters of 10/7 Fr (Applied by Applied Medical Resources) and 14/7 Fr (Retromax™, Boston Scientific, Cook Medical) The larger OD is placed across the UPJ area ordinarily and reversed in lower ureteral strictures. We mostly use the smooth, tapered-profile 10/7 Fr stent. See Figure 53.12.
- Peripheral Stent (Cook Medical) is rarely used now. It was designed without a lumen but with vertical spiral grooves along the stent to expedite drainage. The concept was to keep the ureteral walls apart and allow urine to flow along the grooves.
- Metallic stents are primarily used in the treatment of recurrent ureteral strictures. They are considered an alternative to pigtail stents for their resistance to the compressive force of the stricture, and longer life span. They are made from biocompatiable nitinol (nickel titanium) Since the introduction of the Wallstent, the currently available stents are Memokath 051, Resonance, Allium, and Uventa. Ureteral strictures and obstructions caused by extrinsic pressure do not

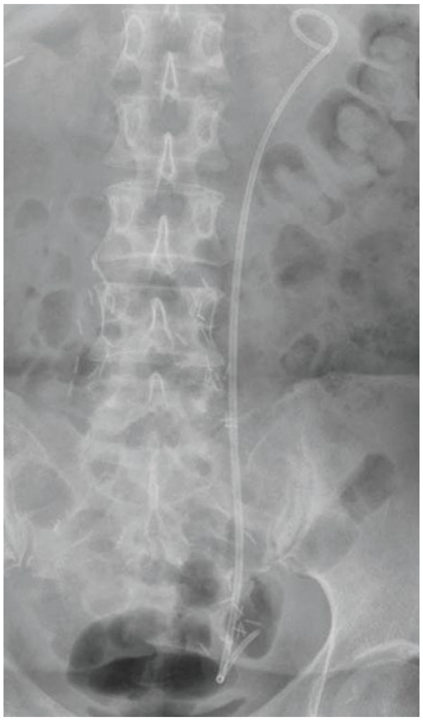

**Figure 53.12** 10/7 Fr endopyelotomy stent placed in reverse after endoscopic treatment of distal ureteral stricture.

drain well with stenting alone despite a short initial improvement. This is because a significant amount of flow is around the stent rather through the stent's lumen, which becomes encrusted.

- Nephrostent 8 & 10 Fr (Boston Scientific): this is a combination of a pigtail and nephrostomy tube. A pigtail stent is ideal after antegrade access and distal ureteral dilation or incision. Once the nephrostomy is cappedit functions as a indwelling stent. This stent can be interchanged over a guidewire and replaced by a single pigtail nephrostomy to allow the urologist to assess the patency of the distal ureter. It is an excellent choice for neobladders, pouches, and inaccessible reimplanted ureters.
- Transplant and pediatric stents (10–18 cm long) are classic double-pigtail stents that are custom-produced for shorter and smaller ureters with material specified for softness or rigidity as required.

## Etiologies of ureteral stricture

Ureteral obstructions and strictures are either intrinsic or extrinsic or a combination of both. They are further categorized as congenital and acquired, with subclassifications of benign or malignant.

### Congenital strictures

Congenital strictures are the most common type of intrinsic stricture (except for UPJ strictures which can be a combination of intrinsic and extrinsic). Categories include UPJ obstruction, ureteral strictures in conjunction with UPJ obstruction, primary obstructive megaureter, ureteral meatal stricture (stenosis), and obstructed ureterocele.

UPJ obstruction will be discussed elsewhere in this chapter but the basic principles of endoscopic incision discussed here apply to that as well. Megaureter is usually diagnosed in children and is defined as dilation of the ureter >7 mm. It can be divided into subsets of obstructive megaureter and refluxing megaureter. Obstructive megaureter is thought to arise from a malformation of the distal ureter at the ureterovesical junction (UVJ), with an aperistaltic segment leading to a small distal portion of stenotic or normal-caliber ureter with proximal hydroureter [38, 39]. See Figure 53.13.

Ureteral meatal stenosis is a congenital pinpoint orifice without previous instrumentation or stone impaction. The ureteral orifice is naturally the narrowest ureteral point of the ureter with an estimated 6 Fr lumen size. If this stenosis is functionally affecting drainage a simple meatatomy or dilation is adequate treatment.

A ureterocele is a cystic outpouching of the terminal ureter occuring in 1 in 4000 children, predominantly females. Some 80% are in ectopic locations, ranging from the bladder to the urethra; 80% are associated with a dysplastic or poorly functioning duplicated upper pole system. Obstructive symptoms in ureteroceles varies in patients and can range from being asymptomatic to having recurrent urinary tract infections (UTIs), hydronephrosis, and renal failure. Ureteroceles cause obstruction due to a stenotic ureteral orifice; however, in severely dysplastic ureteroceles they can also prolapse and cause bladder neck obstruction [40, 41].

### Acquired strictures

Acquired strictures fall into several broad categories: benign, malignant, iatrogenic, and idiopathic. In a review by Tyritzis and Wiklund, 35% of strictures were iatrogenic in nature, 35% had benign causes, 20% idiopathic, and 10% malignant [42].

Open or endoscopic procedures can result in iatrogenic mechanical and vascular damage to the ureter with an estimated occurrence of 0.3–2.5% in pelvic and endoscopic surgery [43]. With the increased volume of minimally invasive laparoscopic and robotic procedures, the overall incidence has increased 30% since 2000, attributed to increased difficulty in visualization and the inability to palpate the ureter compared to open surgery [44].

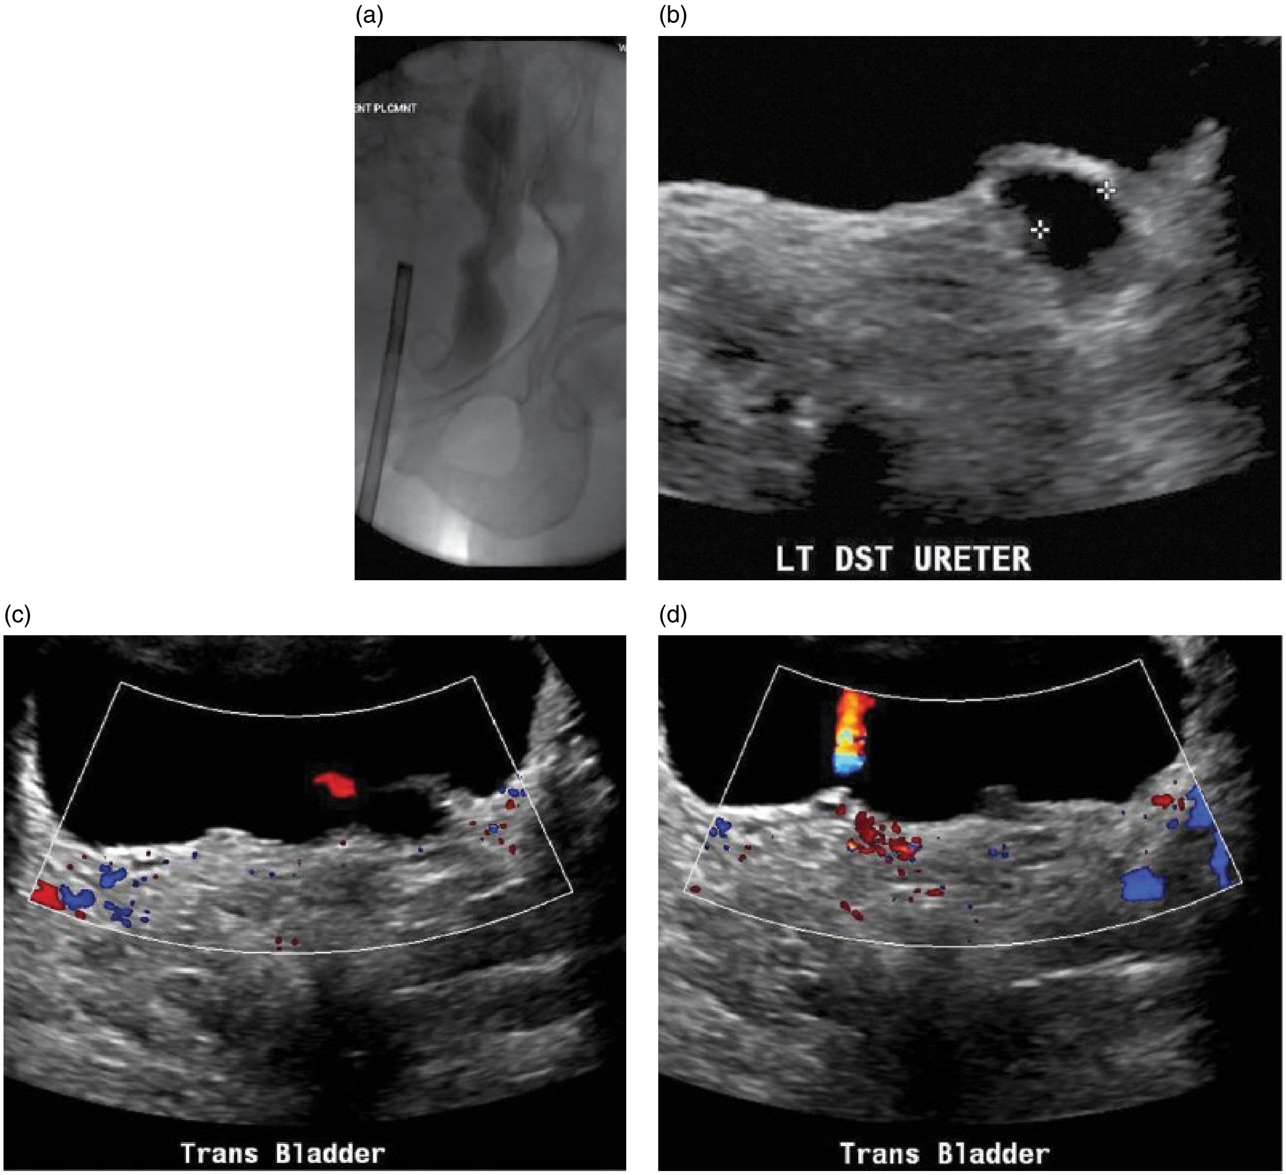

**Figure 53.13** (a) The appearance of a congenital obstructive megaureter. The distal obstructed lumen was incised with a cold-knife endoureterotome. (b) Obstructive megaureter after treatment, note the dilation of the left distal ureter, (c) Sluggish ureteral jet on the left due to poor peristalsis rather than obstruction. (d) Strong ureteral jet on the contralateral side.

Injury can range from thermal mucosal damage to perforation to partial or complete transection. In each case, the ureter or its end vasculture is intrisically damaged, leading to fibrosis and stricture.

The type of surgery responsible for ureteral injuries varies considerably by study. Gynecologic procedures account for 45–74% of ureteral injuries. The injury most commonly seen during hysterectomies occurs in the ureter distal to the crossing of the uterine artery. General surgical injuries account for 4–17%, mostly during colectomies; this is estimated at a rate of 0.3–10% of distal colectomies with the remaining occuring in vascular cases [45].

Urologic surgery accounts for the remaining iatrogenic injuries, estimated at 8–44% of all ureteral injuries during both endoscopic and open surgery. Ureteroscopic injuries are relatively rare, at a rate of 1–3% postinstrumentation. Passage of flexible or semirigid ureteroscopes can cause intraluminal trauma through shear forces, especially if the ureter is insufficiently dilated. A study by Karakan et al. [46] reported higher rates of injury with balloon dilation of the ureter and preoperative UTI.

Insertion of a ureteral access sheath can be associated with iatrogenic ureteral wall injury, especially in unstented narrow lumens. This is due to inserting a larger-diameter device, causing intraluminal shear forces. Holmium laser lithotriposy can cause iatrogenic damage but with penetration of only a few millimeters the damage is less than with Nd:YAG lasers. Nevertheless, accidental energy application, mechanical pressure, and stone fragments can cause localized ischemia and scar tissue. Use of a basket during treatment of stones can result in complete avulsion of the ureter [47]. Fam et al. reported on 77 patients treated endoscopically for impacted ureteral stones, and following the operation found a stricture rate of 7.8% [48].

Iatrogenic ureteral strictures occurring after open urologic procedures such as cystectomy and kidney transplantation are almost always the result of ureteral reimplantation or urinary diversion. Cystectomy has a ureteral anastomosis stricture rate of 2.7–8.8% [49]. In a review by Mano et al. of 1004 renal transplant recipients between 2000 and 2010, 2.6% developed ureterovesical anastomotic strictures [50]. The pathogenesis of ureterointestinal strictures is multifactorial and likely due to ischemia and postsurgical fibrosis [51].

### Benign strictures

Impacted calculi are responsible for up to 65% of benign strictures. The causes of stricture in these patients are multifactorial and intrinsic in nature. Persistent pressure of the stone against the ureteral mucosa and the resulting immune reaction to the stone itself can cause localized ischemia, leading to fibrosis and stricture [52]. Longer stone impaction leads to increased risk: Roberts et al. reported that ureteral stone impaction for longer than 2 months harboured a 24% chance of ureteral stricture, ureteral edema, and epithelial hypertrophy [53]. The edematous mucosa is more fragile and limits endoscopic work space, increasing the chance of mucosal damage [48].

Retroperitoneal fibrosis is a rare, commonly bilateral idiopathic and autoimmune disorder characterized by inflammation and fibrosis around an abdominal aortic aneurysm and surrounding retroperitoneal structures, and it can often cause external ureteral compression [54]. Retroperitoneal fibrosis typically develops as a plaque between the renal arteries and the pelvic brim with rare sacral involvement. As such, the distal ureter is usually unaffected. Retroperitoneal fibrosis accounts for roughly 15% of benign strictures [55] with the majority in the mid and upper ureter with medial deviation. The extrinsic compression leads to a narrow lumen, giving a classicstring-like appearance. The immediate segment above and the pelvicalyceal system are significantly dilated. This process is commonly bilateral.

Endometriosis is the presence of endometrial tissue outside of the uterine cavity and is a chronic inflammatory process stimulating surrounding angiogenesis. Chronic inflammation results in extensive adhesions, distortion, or compression of the ureter in less than 1% of cases [56].

Pelvic lipomatosis can cause compression of the bladder and is associated with possible displacement and narrowing of the distal ureters.

## Infection, trama, and malignancy

Infectious causes of ureteral strictures are rare (<9%), but when present are most often caused by tuberculosis and schistosomiasis [1]. Tuberculosis causes an asymptomatic infection causing destruction along the urinary system with fibrosis and stricture replacing normal tissue during the healing process. Wagaskar et al. reported on 31 patients presenting with urinary tuberculosis, of whom 29% had ureteral strictures [57]. Schistosomiasis is a disease caused by immune reaction to *Schistosoma* eggs, a parasitic flatworm mainly endemic in Africa and the Middle East. The worms migrate to the veins around the bladder and ureters which are extensive, and can affect the bladder and all layers of the ureter, leading to ureteral stricture, bladder neck contracture, and bladder cancer [58]. Al-Shukri et al. reported that ureteral stricture was the most common complication of genitourinary schistosomiasis with 91% of strictures occuring at the distal ureter [59].

Trauma accounts for a very small portion (1–4%) of ureteral strictures. Patients with extensive pelvic fractures and gunshot wounds are prone to these injuries that are usually diagnosed and treated early after the injury occurs. If distal ureteral stricture is a late sequela it can be approached endoscopically.

Malignant ureteral obstruction is caused by direct extrinsic compression of the ureter by local tumor, direct tumor infiltration, or encasement through retroperitoneal lymphadenopathy [60]. Malignant obstruction is often associated with intra-abdominal cancers, but can also be related to metastasis from other sources.

Radiation therapy is commonly used for pelvic malignancies such as prostate, bladder, cervical, uterine, and rectal cancers and the distal ureters, due to their close proximity to these structures, receive scatter radiation. Radiation causes microvascular injury by inducing inflammation in the intima of arteries, and occlusion of smaller arterioles known as obliterating endarteritis, leading to relative ischemia of the ureter [61–63]. Ureteral stenosis from radiation injury develops slowly, between 6 months and 20 years. See Figure 53.14.

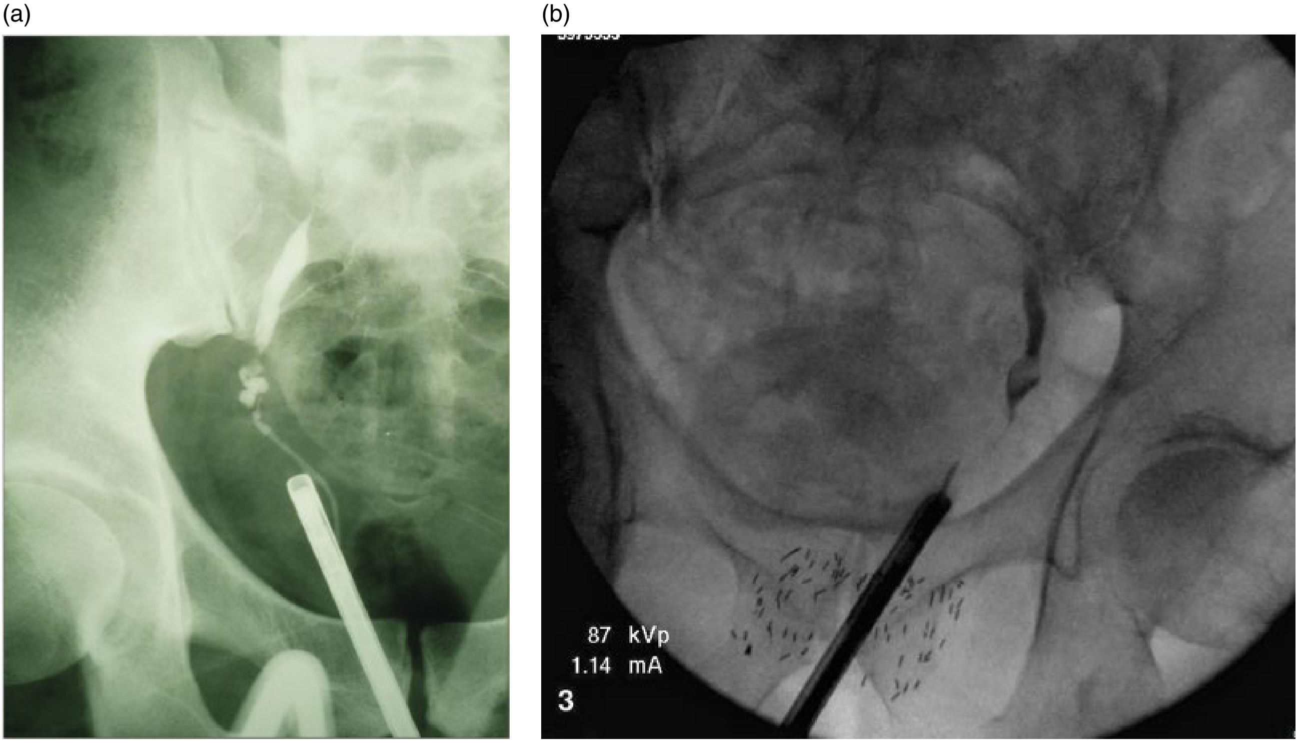

**Figure 53.14** (a) The appearance of a distal ureteral stricture secondary to tuberculosis. (b) Distal stricture secondary to radiation after placement of radioactive seeds causing ischemia of the trigone and intramural ureter.

## Clinical presentation and imaging

The diagnosis of a ureteral stricture depends on the level of suspicion and presentation of the patient. Patients with unknown stricture and few risk factors may present with renal damage and hydroureteronephrosis. They may be completely asymptomatic or have flank pain or recurrent UTIs. In patients with higher suspicion for stricture, strictures may be picked up on imaging before any deleterious effects occur.

### Subjective diagnosis

The most common subjective clinical symptom is dull versus sharp and acute or chronic flank or lower quadrant pain. It can be throbbing in an intermittent or constant pattern with possible radiation towards the groin, decreased urine output, or anuria in solitary and transplant kidneys. Significant abdominal pain, nausea, vomiting, fever, chills, and UTI symptoms similar to an obstructing UVJ stone are not uncommon. One major difference is in transplant patients whose renal arterial and ureteral innervation have been disrupted. Transplant patients do not experience any somatic pain and even in the face of severe hydronephrosis caused by ureterovesical or intramural obstruction due to disruption of renal ureteral nerves. They notice a decrease in urine output, general malaise, or a bloating sensation in lower abdomen. There may be signs of sepsis in advanced cases. Objective findings include elevated creatinine and white blood cell count, tenderness over the graft area, and hydronephrosis on the ultrasound.

### Objective diagnosis

Strictures are typically diagnosed on imaging. Standard CT scan will detect hydroureteronephrosis or raise the suspicion of stricture. Other techniques such as CT urogram, retrograde pyelography, or ureteroscopy are necessary to characterize the exact length and location of stricture. In patients with longstanding stricture, a nuclear MAG3 scan may help determine the extent of renal damage [64]. The most convenient initial evaluation is Doppler renal/bladder ultrasound which can detect hydronephrosis and assess ureteral jets for significant obstruction. Magnetic resonance imaging with hydration clearly outlines the ureter when contrast is contraindicated such as in transplant kidneys (see Figure 53.17, below).

### Treatment strategies

As a principle, except for short strictures or meatotomies in dense strictures that carry infection risk, it is advisable to initially place a stent and allow hydronephrosis to resolve prior to optimal definitive treatment. This passive dilation makes subsequent instrumentation easier and safer.

Meatotomy is a useful technique in treating ureteral meatal stricture. This category includes simple meatal stenosis, ureterocele, obstructive megaureter, and acquired UVJ scarring. Classically, some of these conditions have been treated with open or laparoscopic reimplantation of the ureter, but endoscopic approaches are effective as well [7, 65].

Meatotomy is preformed with meatotomy scissors, laser, or electrocautery. Scissors are preferred because they allow greater control and cause less scarring. The technique involves cannulating the ureteral orifice with a guidewire, followed by insertion of the meatotomy scissors. The right ureteral orifice is accessed with scissors angled posteromedially at the 5 o'clock position and the left at 7 o'clock and an incision is made. This is to preserve the submucosal tunnel and the muscular sheath and conserve the valvular function of the submucosal ureter or medial valve, thus preventing vesicoureteral reflux [66]. Next electrocautery is used if needed. The ureter's blood supply is lateral at this location and one must avoid damage in this direction. Arrabal-Martin et al. found a 94.5% patency rate at 36 months in their 18-patient series [66].

In cases where the stricture extends more proximally, such as in radiation induced cases after radioactive seed implants, the meatotomy can be extended in short bites until a lumen is identified. Balloon dilation and cold-knife endoureterotomy are other options. We do not recommend use of fascial dilators because of the shear effect that can occur after failure of a balloon, which indicates a dense stricture.

## Resection/incision of orifice: post-TURP and TURBT

In some cases of transurethral resection of bladder tumor (TURBT) and transurethral resection of prostate (TURP), a large median lobe or poor visibility can lead to thermal injury to the ureteral orifice, resulting in subsequent stricture. The initial treatment should be meatotomy and stenting, and failure to identify the orifice will require antegrade placement of a guidewire and subsequent dilation or incision with 3–4 weeks of stenting. In some cases, if the surgeon is certain about the location of the orifice, thin-layer resection with a cutting element or a Collin's angled electrode can unroof the obstructed ureter. This should be exercised with extreme caution and prior injection of contrast with columnization to the site of the orifice under fluoroscopic controlcan be helpful.

Balloon dilation is currently used as part of ureteroscopy for initial treatment of stricture or stenotic ureteral orifice. The dwelling time of an inflated balloon should be short in order to limit ischemia. If at maximum inflation pressure the stricture fails to dilate an alternative approach such as endoureterotomy should be used. In such cases the segment of the balloon corresponding to the area of stricture shows a "memory" (or "ring effect") of the failure to dilate the stricture (see Figure 53.6d). This is clearly an additional sign that the stricture is not adequately dilated.

Mechanical dilation with sequential fascial dilators in the early years of ureteroscopy were cumbersome and traumatic. For limited dilation and stretching of the distal ureter prior to ureteroscopy the one-step Nottingham dilator (6–12 Fr) is a reasonable solution if the tight distal ureter does not allow entry of the ureteroscope. The large (12–18 Fr) version should be used cautiously and for the right indications. Forcing a dilator through a stenotic area can result in splitting ("banana peel") of the ureter. Bougie dilators are not commonly used now due to the availability of smaller-caliber ureteroscopes and wider use of balloon dilators.

## Endoureterotomy: cold- and hot-knife incisional treatments

If a distal ureteral stricture does not respond to an initial balloon dilation our preference is perform cold-knife incision of the stricture under direct vision. The orientation of the cutting knife and incision is critical to avoid injury to surrounding structures (Figure 53.4). The half-moon knife sliding over a guidewire provides most control by maintaining an intramural position of the knife. The incision should be performed in *thin layers* for the required length and advanced segmentally, allowing the ureteral wall to expand. The end point is when the tip of endoureterotome reaches a dilated portion of the ureter. Digging or scooping into the wall should be avoided since it causes perforation without adequately incising the length of the stricture. If a straight knife is used, extreme caution must be exercised, extending the blade into the lumen to avoid through-and-through penetration of the tip. For very dense strictures we prefer the Wolf endoureterotome which has a narrower beak profile with a half-moon knife that will travel up and down the ureteral lumen with better control (Figure 53.16).

In the distal ureter a small semirigid ureteroscope can be used since most institutions do not have access to an endoureterotome; thus the urologist can use laser for incision under direct vision. If a straight knife is available it can be used for cold incision. For upper strictures that may be difficult to reach a similar procedure has been performed using laser or a 3 Fr electrode with a flexible

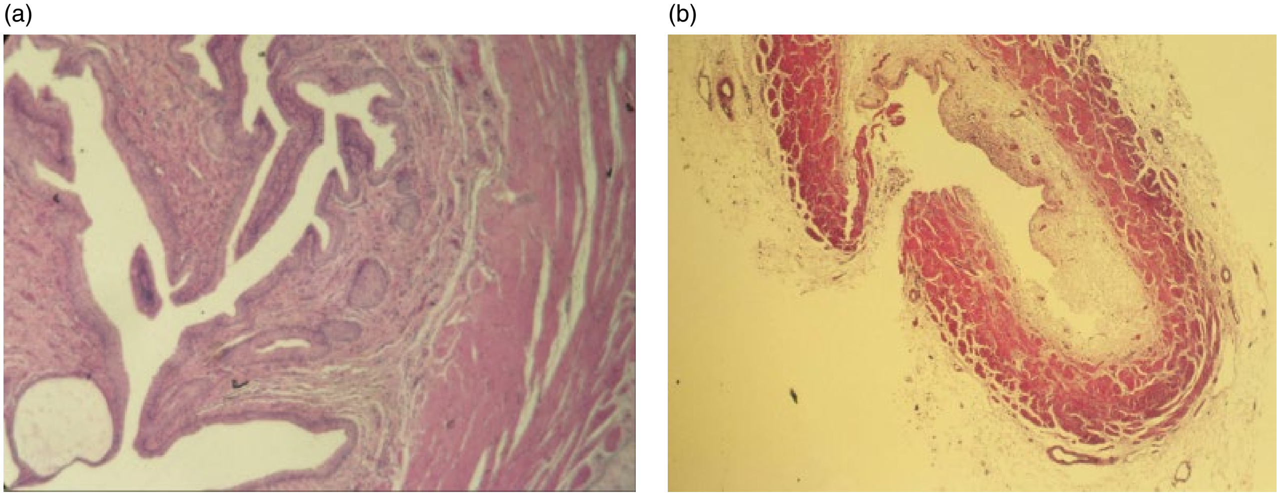

**Figure 53.15** (a) Scarring and disruption of muscle layers after facial dilation. (b) Appearance of ureter after balloon dilation, which shows significantly less damage.

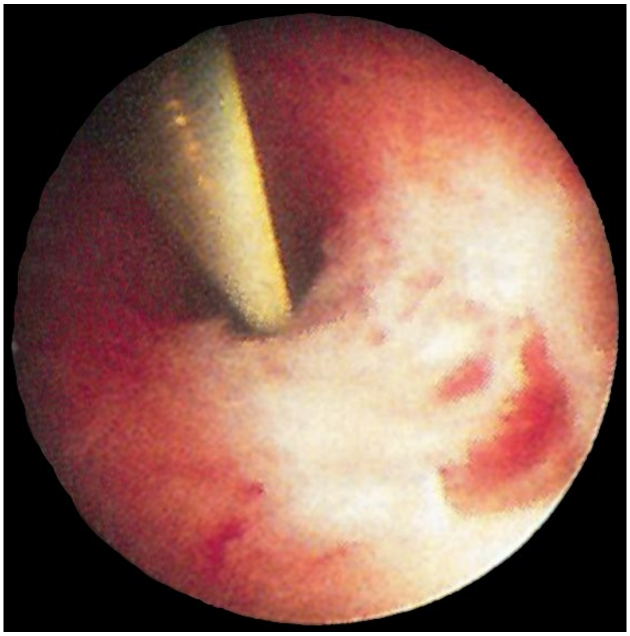

**Figure 53.16** Endoscopic view of endoureterotomy: the incision must be carried out in *thin layers*.

ureteroscope. An angled hot knife can also be used in a ureteroresectoscope with either Storz or Wolf instruments. This is not our preferred choice. Minimal laser and electrical energy should be used to minimize thermal injury to the tissue that already has compromised vasculature.

We generally make an effort to inject the base of the stricture with triamcinolone which may have some benefits in decreasing recurrence, although this may not be supported by level 1 evidence. The dose is 5–10 ml and if injection is not possible, then with irrigation off we flush the base of the stricture with the solution and let it soak for several minutes. In summary, we recommend application of the principles used in the urethra: cold-knife incision and injection of steroids in the stricture area.

## Combined antegrade/retograde management

Synchronous and metachronous antegrade/retrograde approaches are used in cases when retrograde maneuvers have all failed. There are generally two major categories – native and transplant kidneys – as covered here.

### Native kidneys

In this scenario, once the surgeon decides to abort the cystoscopic approach there are two options.

**Synchronous**

In this case the patient is placed in prone position in the split-leg position or on a regular endoscopy table with access to the urethra for flexible cystoscopy. After the urologist performs a percutaneous access a guidewire is inserted into the bladder in an antegrade fashion and retrieved with the flexible cystoscope and the dilation is done over the through-and-through wire followed by stenting. Neobladders and continent pouches can be managed in the same fashion. Similar to urethral stricture, an antegrade/retograde "cutting-to-the-light" technique has been used in managing ureteral strictures. We have found this to be useful only in short and fresh strictures. Long ureteral segments with poor vasculature have a high recurrence rate.

**Metachronous**

If the urologist decides not to proceed any further after the failed retrograde approach, percutaneous nephrostomy and antegrade manipulation can be done by interventional radiology. Management of a distal stricture is usually dependent on institutional policy or the urologist's preference to complete the procedure in a retrograde manner.

### Transplant kidneys

We usually prepare the patient for a simultaneous retrograde/antegrade approach with the patient in lithotomy position, since the kidneys are transplanted in the lower quadrant. C-arm and ultrasound monitors are placed on the opposite side of the kidney. In this arrangement both surgeons at the foot and side of the patient can monitor the procedure. The video monitor is best located over the patient's chest. A percutaneous nephrostomy is performed with ultrasound guidance or fluoroscopy; after access is secured a guidewire is directed into the bladder. It is not unusual for the wire to curl up above the stenotic ureter. A Kumpe or Cobra catheter is usually helpful to negotiate the tip of the wire into the bladder and the rest of the procedure is usually completed cystoscopically. One important difference between native and transplant distal ureter is that in the latter it is actually upper ureter and sometimes a short part of mid ureter that is anastomosed to the bladder; this has fewer muscle layers and is less resistant to shear forces and incision.

In rare situations when the orifice is occluded and cannot be cannulated we have approached it antegrade with a flexible ureteroscope and lasered across the obstructive membrane or trapped mucosa. An alternative approach is the placement of a ureteral catheter flush with the very terminal end of the ureter and to use a sharp metallic guidewire to penetrate into the bladder. This must be monitored cystoscopically to ensure the correct direction and orientation. If the wire is completely secure within the ureteral catheter, attachment of Bovie to the terminal end of a metal wire creates a cutting Bovie effect. This maneuver must be reserved for very rare cases and performed with caution and careful antegrade/retrograde control to stay intraluminal. With the use of modern endoscopic equipment and small-caliber lasers it is rare to need such an approach. We have used this maneuver in three transplant kidneys in the last 27 years.

## Stenting

Different stents are almost always needed as an adjunct after other therapy for ureteral strictures. Based on the length, severity, and etiology of the stricture, our practice is to use a 22–24 cm-long 4.8–5 Fr stent in the majority of our routine ureteroscopies which is quite comfortable for patients. In rare cases of long, tortuous ureters, and in the upper moiety of a duplicated system we use a 26 cm stent. Using the shorter stent prevents excessive contact and irritation of the trigon and bladder neck which is the main cause of a patient's irritative symptoms. Most strictures are managed with a 6 Fr stent. In long and dense strictures we use a tapered endopyelotomy stent in a reverse fashion, so the distal ureter is stented with the 10 Fr segment. Routine postoperative antibiotics are used in all patients and modified based on pre-existing or newly diagnosed infections, with anticholinergics or alpha-blockers as needed to ease irritative symptoms. Antibiotic-coated stents are not yet widely used.

### Follow-up protocols

The follow-up protocol directly depends on etiology, degree, length of the stricture, nature of the operation, surgeon's preference, and a host of other factors and comorbidities. Stent use is beneficial during the healing process, prevents extravasation of urine, and keeps luminal patency. On the flip side, stents can be a source of inflammation, and muscular and epithelial hyperplasia. Kerbl et al. compared different lengths of stent placement (1, 3, or 6 weeks) following endoscopic incision in a pig model and found no significant overall differences among the mean values [67]. Without a consensus on the needed duration of stenting, a period of 3–4 weeks would be reasonable for short and non-dense strictures. The majority of the literature data are based on 4–6 weeks of stenting; that is, the original Davis–Oppenheimer data [68] and endopyelotomy data described in 1986 [69], with some later data suggesting that a shorter period is adequate [70]. Patients with chronic or recurrent strictures may benefit from a silicone stent (Cook Medical) with an indwelling time of over 6 months with minimal encrustation. The size of stent is also a field of controversy. *In vivo* studies on pig models have shown no difference in patency, with larger stents being associated with higher rates of UTI, while a retrospective study by Wolf et al. showed an improved patency rate with stents larger than 12 Fr.

### Follow-up studies

The patient's clinical performance is the initial subjective postoperative assessment. Flank pain, fever, nausea, or vomiting can be some of the early warning signs of immediate recurrence or failed treatment. The interval also depends on the degree of pretreatment dilation and reservoir of the upper tract. As such, it may take a week or longer for patients with a previously dilated upper urinary tract to become symptomatic after recurrence of obstruction. In some cases of very chronic obstruction and poor renal function, patients with low urine production ("dry well") due to low renal pelvic pressure may never manifest classic symptoms of obstruction; therefore, objective assessment is required.

Our initial recommendation is renal ultrasound 2–3 weeks poststent removal. If this study is satisfactory, follow-up renal and bladder ultrasound with assessment of ureteral jet is recommended at 3 months in asymptomatic patients. A diuretic renal scan is recommended to quantfy function and drainage of the renal moiety if there is concern. A CT, MR urogram, and hydration diuretic MR urogram without contrast can all be very valuable for follow-up. See Figure 53.17. After the initial evaluations we usually rely on periodic ultrasound or occasional diuretic nuclear scan or CT/MR urogram. Unresolved situations in a symptomatic patient will need retrograde pyelogram and endoscopy. In patients with good renal function a virtual ureteroscopy can be valuable for assessing intraluminal space [64, 65, 69, 71–73].

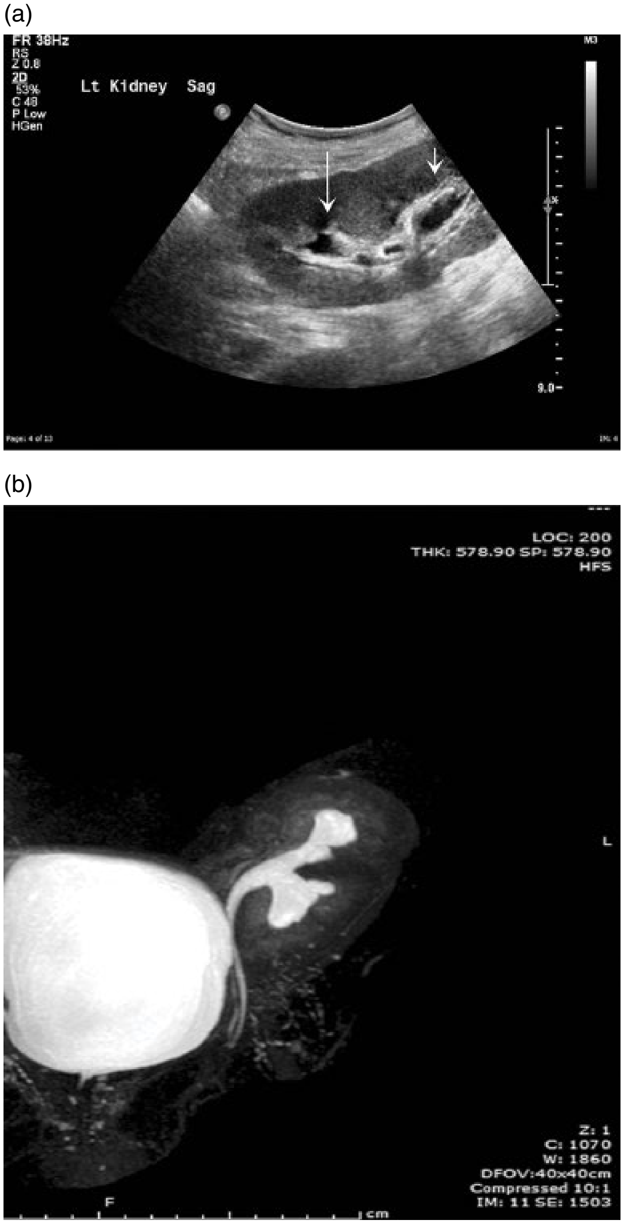

**Figure 53.17** MR urogram with hydration and without contrast in a left lower quadrant transplant kidney ruling out distal stricture.

See Video 53.2.

## Clinical outcome and analysis

Clinical studies have shown that endourological management of ureteral strictures varies due to the use of different modalities and lack of a uniform approach and stenting protocol, thus making a scientific analysis and comparison to open or laparoscopic techniques quite unrealistic. The decreased morbidity and sometimes ease of operation often make this approach a preferable first step.

### Stenting

Often the first step in treating a ureteral stricture is a stent or a percutaneous nephrostomy. Success rates for retrograde stenting have been reported at 75–88% for both extrinsic and intrinsic obstruction [74, 75]. However, the use of double-J stents for extrinsic ureteral obstruction has been associated with a high failure rate in long-term follow-up. Double-J stents rely on flow around the stent for drainage rather than intraluminal flow [75]. The type of pelvic malignancy likely plays a role in the differing success rates. In a study by Ganatra and Loughlin of 157 patients, obstruction by bladder, prostatic, or cervical cancer had a success rate of 15–21%. Invasion seen on cystoscopy was associated with a threefold failure rate [76]. Chitale et al. evaluated a staged approach to malignant ureteral obstruction with nephrostomy under local anesthesia and 1–2 weeks later antegrade ureteral stent. In the series, 24 out of 65 patients had an attempt at retrograde stent placement with a 21% success rate, while the staged approach had a 98% success rate [77].

The use of metal stenting to overcome malignant ureteral obstruction is controversial. Liatsikos et al. used metallic stents in 50 patients with a technical success rate of 100% for stenting of the stricture [60]. The immediate stricture patency rates in patients with extrinsic malignant ureteral obstruction and in patients with benign ureteral obstruction were 100 and 44%. Kim et al. [78] demonstrated poor long-term efficacy of self-expandable segmental metallic stents (Uventa) in chronic strictures with a success rate of 34%. Notably, 28% experienced major complications (≥Clavien-Dindo class IIIb), such as

**Table 53.1** Ureteral patency after treatment.

| Study | No. of patients | Etiology | Type of stent | Patency rate (%) | Mean follow-up (months) |
|---|---|---|---|---|---|
| Rosevear et al. [79] | 8 | Extrinsic, benign | Double J | 100 | 16 |

uretero-arterial, ureteroenteric, or ureterovaginal fistula, ureteral perforation, uncontrollable bleeding, and complete obstruction [78]. See Table 53.1.

## Balloon dilation

Balloon dilation of the distal ureter was first reported to be safe in a study by Clayman et al. in 1987 [88]. They showed that slow dilation produced less residual inflammation at 6 weeks. One week after dilation, trauma in the form of circumferential edema and thinning of the muscularis propria was present, but resolved by 6 weeks. See Table 53.2.

Ravery and colleagues presented their results of 11 ureteric strictures in patients with inflammatory strictures (tuberculosis, iatrogenic injury, radiation therapy, and parasitosis). Balloon dilation was performed at 10–20 atm for 5–15 minutes. With a mean follow-up of 16 months, the long-term success rate was 40% [89]. Richter et al. studied 127 patients with malignant ureteral strictures, 46 via balloon dilation (antegrade), wall stents in 31, endoureterotomy in 37, percutaneous ureteroneocystotomy in 34, and bougie and stents in 13 [81]. They found that balloon dilation was only successful in short benign ureteral strictures with intact vascular supply. Byun et al. evaluated 43 ureteral strictures: 22 malignant and 21 benign. The success rates at 36 months were much higher for benign then for malignant strictures (57 vs. 14%, $P < 0.001$). No patients with strictures greater than 2 cm were successfully dilated, supporting the use of balloon dilation for short benign ureteral strictures [90].

Overall success rates ranged from 50 to 82% in published studies [91–95]. The large discordance is success rates likely reflects the differing inclusion criteria and etiology. There still remains no consensus of the optimal balloon size and technique for the procedure. In the studies cited here, the number of cycles (1–10), balloon size of 4–10 mm, duration of inflation (up to 10 minutes), and stent size (6–16 Fr) were not uniform [96, 97].

A study by McIntyre et al. examined 1784 patients who underwent radiation for cervical cancer from 1960 to 1989 and found a 0.15% risk of developing distal ureteral stricture per year, culminating at 2.5% incidence at 20 years [98].

With improvement in endoscopic techniques and equipment, it is now the preferred initial treatment for benign ureteral strictures. Treatment success rates have been reported to range from 53 to 82% and appear to have increased success with shorter strictures and non-ischemic strictures [42].

Eshghi and Schwalb reported on 25 distal ureteral strictures, mostly postsurgical, with various lengths, dilated to 18 Fr. The 36 month success rate was 74% [99]. Liatsikos et al. examined the use of self-expanding metallic ureteral stents in 90 patients over a median of 15 months with a patency rate of 51% [100]. The Memokath 051 ureteral stent (a nickel-titanium stent) showed a success of 92% [97]. Due to its lower success rate compared with endoscopic incision modalities, balloon dilation is best reserved for short areas of stricture [89, 96, 101–103]. Overall, balloon dilation has a lower success rate then endoureterotomy and should likely be reserved for use only in short, non-ischemic strictures, if endoureterotomy is not feasible or significant comorbidities limit treatment options.

### Endoureterotomy

Endoureterotomy has multiple approaches with similar success rates. The different techniques – cold knife, the Acucise device, lasers, and electrocautery – are all summarized in this chapter. Success rates vary secondary to technique, etiology, and location. Overall success rates were 70–100% in reviewed studies, better than for balloon dilation.

Lopatkin et al., reported on 21 patients treated with retrograde cold-knife incision for their ureteral or UPJ strictures including seven strictures in the mid to distal ureter over a 22 month period, with a success rate of 86% in the ureter [104]. Schneider et al. also reported on using cold knife for 13 primary and 43 patients with secondary obstruction of the UPJ or ureter with a success rate of 83% at 15 months for distal stricture [110]. Wolf et al. reported on 38 endoureterotomies with a success of 78% at 28 months [64]. Factors associated with failure of endoureterotomy was renal function less than 25% an ischemic etiology and complete obstruction. In strictures >1 cm, the use of a stent >12 Fr and injection of triamcilinone improved outcomes.

Chandhoke et al. reported on the Acucise cutting balloon catheter on 28 patients with UPJ or ureteral obstruction, including five in the distal ureter. The symptomatic success rate was 80% in the distal ureter at 3 month follow-up [105]. Cohen et al. reported 29 month follow-up success, defined as radiographic resolution or symptom relief, in 80% of the distal strictures [106]. Preminger et al. reported on a multicenter trial on 40 ureteral strictures with a patency rate of 58% in the distal ureter [32].

Singal et al. reported use of holmium laser followed by balloon dilation on 12 ureteral strictures with a success rate of 78% at 9 months [107]. In a study by Ibrahim et al., 55 patients with a mean stricture length of 1.92 cm underwent retrograde laser endoureterotomy. Patients were randomized into single ureteral stent or double ureteral stent for 8 weeks after therapy. They found an overall successful treatment rate of 67%, and for strictures >1.5 cm the double ureteral stent had a success rate of 82% compared to 39% for a single ureteral stent [97, 108].

Eshghi and Schwalb reported on 61 strictures treated with a cold-knife endoureterotome and endoureterotomy scissors with no immediate side effect and 96% success at 24 months [99].

Ureterointestinal anastomotic strictures treated with cold-knife endoureterotomy and stent placement showed success rates at 1, 2, and 3 year follow-up of 86, 67, and 60% respectively [109]. See Table 53.3.

### YAG laser

In a study of five patients treated with YAG laser endoureterotomy for anastomotic stricture in transplanted kidneys, 100% had resolution of stricture at a median follow-up of 52 months [111]. Gnessin et al. reported on 35 patients with benign strictures treated with YAG laser endoureterotomy: 14 had distal ureteral strictures at 27 months and 78% had resolution of stricture. Most failures occurred within less than 9 months of surgery [112]. Mano et al. treated nine patients with ureterovesicular strictures posttransplantation with either cold-knife or YAG endoureterotomy with a success rate of 83% at 44 months [50]. Han et al. reported a success rate of 76.5% out of 77 patients over a median of 19.6 months. Stone disease, positive presenting symptoms, and short length of the stricture were identified as variables with a good predictor [113].

## Summary and conclusions

The most essential aspect of endoscopic and endourologic management of distal ureteral stricture is an initial thorough assessment of cause, severity, length, and vascular

**Table 53.3** Endoureterotomy for benign ureteral strictures.

| Study | No. of strictures total (distal) | Technique | Success rate total (distal), % | Follow-up (months) |
|---|---|---|---|---|
| Lopatkin et al. [104] | 7 (4) | Cold knife | 86 (100) | 22 |
| Schneider et al. [110] | 12 (12) | Cold knife | 83 (83) | 15 |
| Chandhoke et al. [105] | 8 (5) | Acucise | 75 (80) | 4 |
| Cohen et al. [106] | 8 (5) | Acucise | 75 (80) | 29 |
| Preminger et al. [32] | 40 | Acucise | 55 (58) | 9 |
| Wolf et al. [64] | 38 (29) | Cold knife | 82 (78) | 28 |
| Singal et al. [107] | 10 (12) | Holmium laser | 67 (70) | 11 |
| Eshghi and Schwalb. [99] | 61 | Cold knife | 98 | 24 |

viability of the stricture. The coexisting risk factors and comorbidities will further define the path towards the treatment. An adequate training in endoscopic and interventional techniques along with a wide variety of instruments are basic requirements for treating challenging cases with altered anatomies. As a rule, once access has been secured across a stenotic area in most cases balloon dilation with 3–6 weeks of stenting provides an acceptable success rate. In more complicated cases staged procedures and use of dedicated instruments such as the cold-knife endoureterotome is recommended for better results. The dilemma is that, similar to other entities such as renal ureteropelvic tumors there are no standardized techniques or protocols to provide an adequate number of cases with level 1 evidence to allow definitive statements about some of these treatment modalities. With more time and expanded use of these techniques such recommendations will come to fruition.

# Endoscopic Management of Ureteroenteric Strictures

*Thomas Masterson & Robert Marcovich*

*Department of Urology, University of Miami Miller School of Medicine, Miami, FL, USA*

## Introduction

Ureteroenteric strictures (UES) represent an uncommon, but potentially devastating and difficult to treat complication of urinary diversion. UES may occur in 4–8% of cases [1, 2]. Open surgical repair is the gold-standard therapy, with reported long-term success rates of up to 80%, but it can be very difficult, with greater morbidity due to scarring and intra-abdominal adhesion formation [3–6]. The decreased morbidity of primary endoscopic management, as well as the continued refinement of endourologic equipment and techniques, has led to increased interest in this approach despite inferior outcomes compared to open revision. Uniformly, endoscopic treatments result in lower blood loss and length of hospital stay, as well as rapid recovery [7]. Initially felt to be suitable only for those unfit for open repair, endourologic management is now typically offered as first-line treatment. Due to the relatively low incidence of UES, most studies evaluating primary endoscopic therapy are small, which impairs direct comparison of modalities. Often, patients with UES are eliminated from larger studies evaluating the utility of endoscopic techniques for benign stricture disease. Additionally, no randomized studies comparing open and endoscopic management exist.

In this chapter we examine the current literature and published techniques pertaining to endoscopic management of UES.

## Background

Most nonmalignant strictures manifest within 2 years of the initial urinary diversion [8] and multiple factors are believed to contribute to their occurrence. Benign UES have been reported in all types of urinary diversions and are thought to be associated with ischemic changes in the ureter [9]. Multiple studies have noted an increased stricture rate on the left side, possibly related to the greater degree of ureteral dissection, as well as tunneling and kinking of the ureter through the mesentery [4, 8–11]. Several studies have investigated effects of technical variations at the time of diversion, although some are contradictory or provide results that do not reach significance due to a lack of subjects and statistical power. A running suture at the anastomosis may increase the incidence of strictures [12]. Use of a nonrefluxing anastomosis has been shown to raise the rates of stricture formation in comparison to a refluxing anastomosis [13]. The most studied technical consideration has been comparison of the Wallace (adjoined ureters implanted end to end) and Bricker (individually implanted) ureteral anastomoses, which has generally shown no difference in stricture frequency [10, 14]. The use of ureteral stents at the time of anastomosis is also controversial. Historically believed to assist in healing and alignment, and decrease the risk of urine leak, other studies have associated ureteral stenting with a greater likelihood of infection, and possible increased stricture formation [15–17]. Body mass index of $>30\,\mathrm{kg/m^2}$ and prior pelvic radiation [10] are also thought to influence the risk of developing a stricture.

## Presentation and diagnosis

Signs and symptoms of UES can include flank pain, malaise, failure to thrive, pyelonephritis, sepsis, hematuria, and worsening renal function [18, 19]. Some patients may develop strictures slowly and remain asymptomatic with only a rising creatinine level. This heterogeneity in

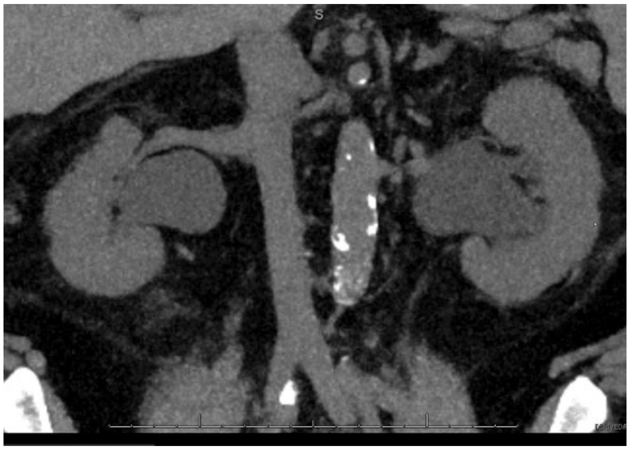

**Figure 54.1** Coronal CT scan showing bilateral hydronephrosis in a patient with bilateral uretero-ileal anastomotic strictures following radical cystectomy.

presentation necessitates routine laboratory and radiographic surveillance and close clinical follow-up [20]. Initial evaluation generally consists of serum chemistries and radiographic imaging. Renal ultrasound or computed tomography (CT) are most frequently utilized in the screening of hydronephrosis (Figure 54.1). Since reflux can mimic obstruction, it should be ruled out with other anatomic or functional studies. Free reflux of contrast into the ureter on loopography essentially excludes anastomotic stricture. If no reflux is seen on loopogram and renal function is adequate, renal scintigraphy can aid in the diagnosis of obstruction. Antegrade contrast studies such as intravenous urography, CT urography, and antegrade nephrostogram can also help diagnose a stricture and characterize its length and location as well as evaluate for filling defects that may herald recurrence of malignancy. Such a recurrence is relatively rare in comparison to benign etiologies of stricture, but should be considered if appearing at more than 6 months after initial diversion [21–23]. Urine cytology and biopsy may be indicated before definitive treatment of the stricture.

## Indications for therapy

Patients who develop symptomatic strictures generally require early relief of obstruction. Asymptomatic patients also benefit from decompression, as poorer treatment outcomes have been observed with an ipsilateral renal function of less than 25% [24]. Indications for urgent intervention include intractable flank pain, obstructive pyelonephritis, rising creatinine, and impending sepsis. Due to the inherent difficulty of retrograde approaches in patients with urinary diversions, percutaneous nephrostomy is most often utilized to relieve obstruction. Placing a nephrostomy tube also facilitates antegrade diagnostic studies to assist in stricture localization, characterization, and surgical planning.

## Endourologic techniques

Treatment of UES has largely developed from techniques used for ureteral stricture disease. Approaches can be retrograde, antegrade, or a combination of both. Because initial management of UES involves decompression of the collecting system with a percutaneous nephrostomy, this, in combination with the technical challenges of identifying the ureteral anastomosis in a conduit or neobladder, make an antegrade approach preferred.

Since the key manipulations required to treat UES occur in the distal ureter, it is important to have a percutaneous access which will allow easy passage of instruments to this area. Therefore, upper pole or upper interpolar renal access is preferable to lower pole access. If the patient has a lower pole nephrostomy tube that was previously placed simply to drain the kidney, strong consideration should be given to relocating the access to the upper or mid collecting system. If the patient does not have a nephrostomy tube at the time of definitive management, access is usually obtained with ultrasound guidance and confirmed with fluoroscopy. A urine culture should be obtained and any bacteriuria treated prior to definitive endoscopic treatment of a UES.

Video 54.1 demonstrates endoscopic treatment of UES in detail. After induction of general anesthesia, patients with ileal conduits are placed in flank position to provide easy access to the nephrostomy as well as the urostomy, and both the flank and abdomen are sterilely prepared and draped. For left-sided strictures, which are most common, the patient is placed in the right lateral decubitus position and for right-sided strictures the patient is positioned in left lateral decubitus. Standard cushioning done for flank approaches, including an axillary role, is utilized. Patients with neobladders are positioned prone with a urethral catheter in place. The technique used for a patient with a neobladder is similar to that used for a benign ureteral stricture treated with an antegrade approach, so the following description will be limited to the method used for patients with ileal conduits.

The procedure begins with antegrade injection of contrast through the nephrostomy to demonstrate the stricture (Figure 54.2) and the renal and ureteral anatomy, as well as to assess for any filling defects in the kidney and ureter. A 0.038 or 0.035 inch hydrophilic tip guidewire is passed through the nephrostomy tube into the collecting system and manipulated through the ureteropelvic junction and down the ureter. Various 4 or 5 Fr angle-tipped

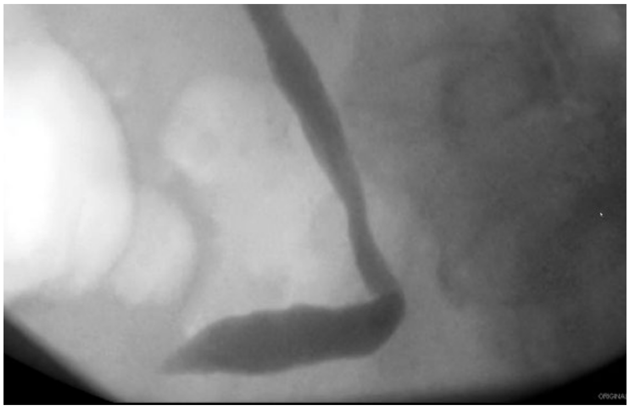

**Figure 54.2** Antegrade nephrostogram showing left ureter tapering to a stricture, with no contrast seen beyond the stricture.

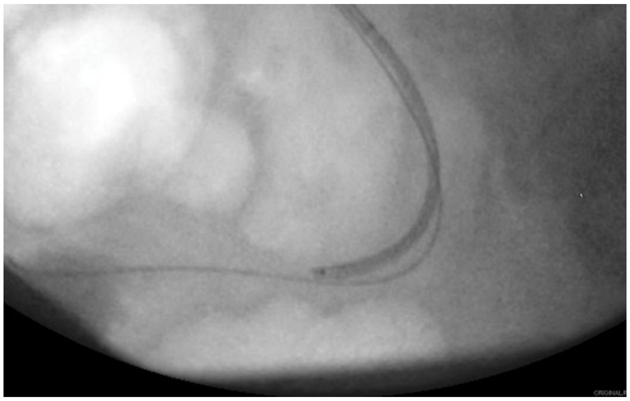

**Figure 54.3** Radiographic view of flexible ureteroscope examining left uretero-ileal anastomotic stricture. Guidewire is through the stricture into an ileal conduit.

catheters (Kumpe™, Cobra™) can assist in these manipulations. After incising the fascia along the wire with a scalpel, an 8/10 Fr coaxial dilator/safety wire introducer is passed over the working wire. A safety wire can then be placed down the ureter. Next, a 13 or 14 Fr short ureteral access sheath is advanced over the working wire. Further dilation or placement of a larger sheath is typically unnecessary. The renal collecting system and ureter can then be examined with a flexible fiber-optic or digital ureteroscope (Figures 54.3 and 54.4). Any suspicious lesions should be biopsied at this point. If the ipsilateral ureter happens to be very dilated, the tract can be upsized to a larger access sheath using an Amplatz dilating system, and an 18 Fr sheath can be placed in order to use a flexible cystoscope for subsequent manipulations. However, this is not typically necessary.

After establishing working access, any of the various treatment modalities reviewed herein can be employed. At the conclusion of treatment a ureteral stent is positioned to maintain patency during healing.

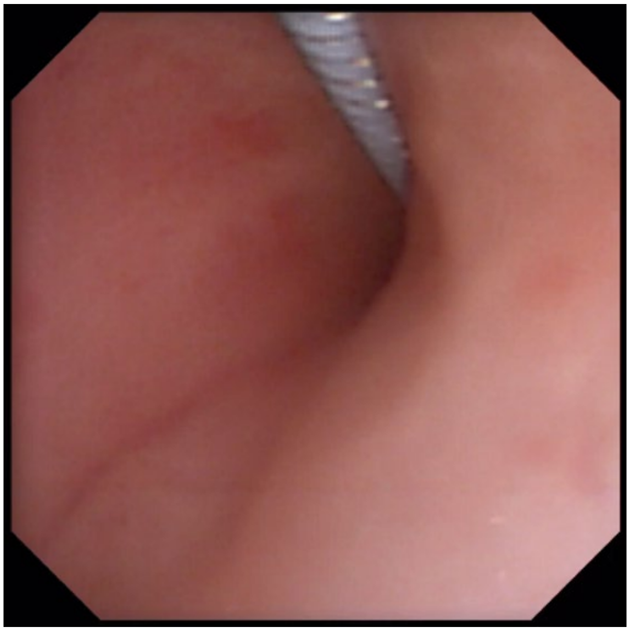

**Figure 54.4** Digital flexible ureteroscope view of uretero-ileal stricture with guidewire passing through the stricture. The area is too narrow to advance the ureteroscope close enough to perform laser endoureterotomy.

## Balloon dilation

The use of balloon dilation in urology was first described in the nineteenth century for the treatment of urethral strictures [25]. It was not until the 1980s that dilation was used in the treatment of ureteral strictures [26]. Since then, the use of ureteral balloon dilation has become commonplace in endourology. Balloon dilation may be used as primary endoscopic treatment, or in combination with other modalities. An advantage of balloon dilation when used as monotherapy is that it can be accomplished under local anesthesia and can be done by an interventional radiologist. The renal tract does not need to be dilated nor a working sheath placed. Once wire access is established, the dilation balloon is positioned under fluoroscopic guidance across the strictured area. The balloon is then slowly inflated with diluted radiographic contrast media until it assumes the typical hourglass shape caused by the stricture. Inflation continues until the hourglass shape gives way and the balloon is completely inflated (Figure 54.5). The dilation is then held for approximately 3–5 minutes before deflation. This cycle may be repeated as necessary until the entire stricture is treated. Figure 54.6 shows the endoscopic appearance of a UES immediately after balloon dilation.

## Endoureterotomy

Endoureterotomy, or incision of the ureter, was introduced due to the disappointing long-term success of

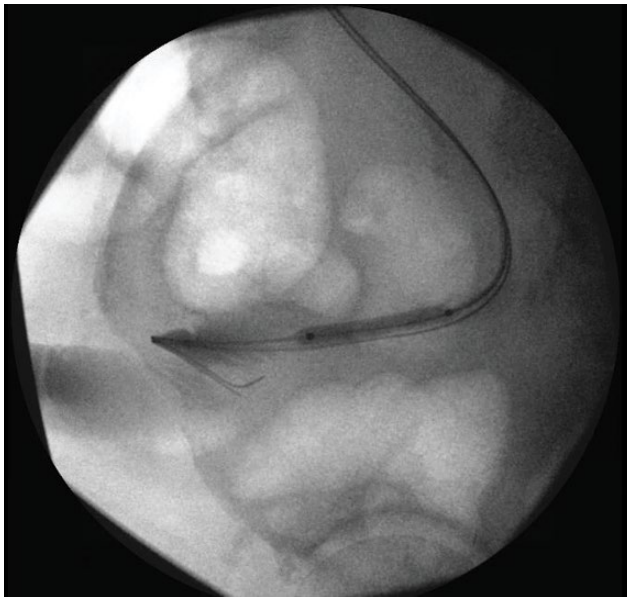

**Figure 54.5** Radiographic view of an inflated balloon catheter dilating a stricture.

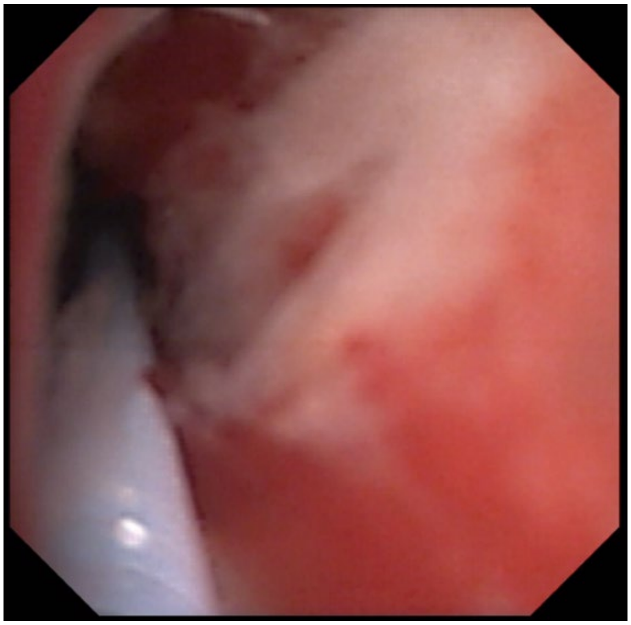

**Figure 54.6** Endoscopic view of a stricture after balloon dilation. The passage to the ileal conduit can be seen in the upper left quadrant.

balloon dilation. Endoureterotomy may be performed using a variety of instruments, including cold knife, electrocautery, or laser. Additionally, the Acucise™ cutting balloon catheter combines electrocautery with balloon dilation of the ureter. The primary goal of each modality is to create a full-thickness incision that extends approximately 1 cm beyond each end of the stricture and into peri-ureteral fat. This is confirmed by visualization of peri-ureteral fat or extravasation of contrast on fluoroscopy [27]. For dense strictures, endoscopic injection of 3–5 ml of 40 mg/ml triamcinolone into the incised stricture has been advocated to improve outcome [24, 28].

### Cold-knife endoureterotomy

Cold-knife treatment typically requires a semirigid ureteral resectoscope for retrograde incision of the stricture. Because of the larger diameter and lack of flexibility, the extent of narrowing that can be treated under direct vision is limited. An alternative method has been described in which a flexible wire-mounted cold knife is passed antegrade through a nephrostomy and then withdrawn to perform an endoureterotomy [29]. This may be performed under fluoroscopic guidance or visually in conjunction with a ureteroscope. Regardless, several incisions may be required. Cauterization of urothelial or mucosal bleeding is not necessary and should be avoided because of the risk of thermal damage [30]. Ureteral stents are typically utilized as the ureter heals.

### Electrocautery endoureterotomy

Electrocautery is typically performed under direct visualization through a semirigid or flexible ureteroscope. Safety wires should be insulated to avoid application of electrical current outside the target treatment area. A 2 or 3 Fr Greenwald electrode is advanced through the ureteroscope and incision is made on pure cutting current at a power of 75 W. Multiple controlled incisions into the fibrotic tissue may be made under direct visual control. It is challenging, but imperative, to maintain precise, linear, incision tracking with a flexible ureteroscope to avoid surrounding thermal damage. Lovaco and associates reported a method in which a guidewire is passed antegrade and a dilation balloon is passed retrograde, inflated at the stricture, and pulled down to intussuscept the stricture into the bowel segment. The stricture is thus well exposed and can be incised precisely from below [19]. This method seems to provide a theoretical advantage of decreased injury to retroperitoneal blood vessels and bowel, but no subsequent publications of this technique have been forthcoming.

### Acucise balloon catheter endoureterotomy

The Acucise™ cutting balloon catheter (Applied Medical, Rancho Santa Margarita, CA, USA), comprising a monopolar electrocautery cutting wire and a 24 Fr 3 cm balloon can be used to treat strictures throughout the ureter [31]. After identification of the stricture, the device is deployed over a guidewire and positioned so the radiopaque markers straddle the stricture. Special attention must be given to the location of the cutting wire after visual inspection to avoid any peri-ureteral vessels.

Treatment begins with inflation of the balloon with 2 ml of dilute contrast media along with simultaneous activation of the cutting wire at 75 for a maximum of 5 seconds. Similar to pure balloon dilation, Acucise balloon inflation may be maintained for 3–5 minutes. The manufacturer suggests no more than two treatments be undertaken at one time. Presence of a safety wire during electrocautery activation is not recommended because of potential conduction injury.

### Laser endoureterotomy

Laser endoureterotomy for UES may be performed with a variety of lasers, but the holmium:YAG laser is preferred because of its favorable safety characteristics with a depth of tissue penetration of only 0.4 mm [27]. Incision is performed visually through a flexible ureteroscope with a 200 µm fiber set at 1 J and 10 Hz (10 W) (Figures 54.7 and 54.8). Direct visual inspection prior to incision is necessary to avoid any pulsations representing peri-ureteral vessels and, afterwards can confirm the presence of fat. Again, care must be taken to make precise cuts to avoid thermal damage to a wide area of the ureteral circumference, which can be quite challenging with a flexible ureteroscope. After incision, contrast injection into the ureter should reveal extravasation (Figure 54.9).

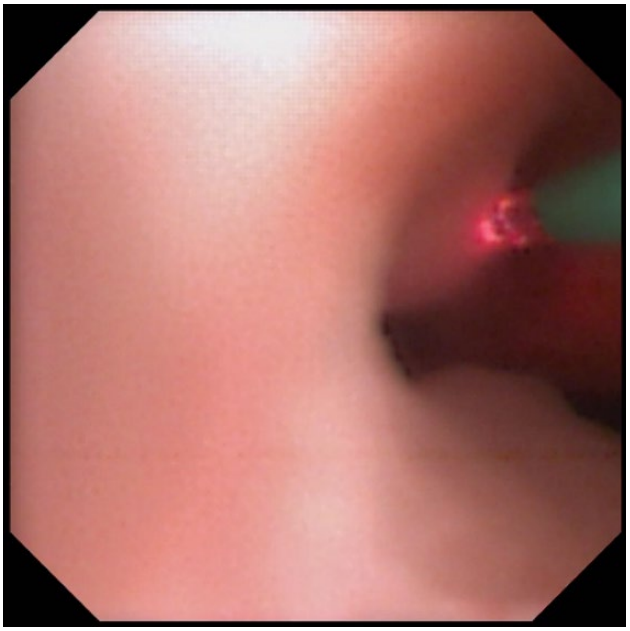

**Figure 54.7** A 200 µm holmium laser fiber poised to perform endoureterotomy. The laser is positioned just inside the conduit and drawn back through the stricture into the ureter (see Video 54.1).

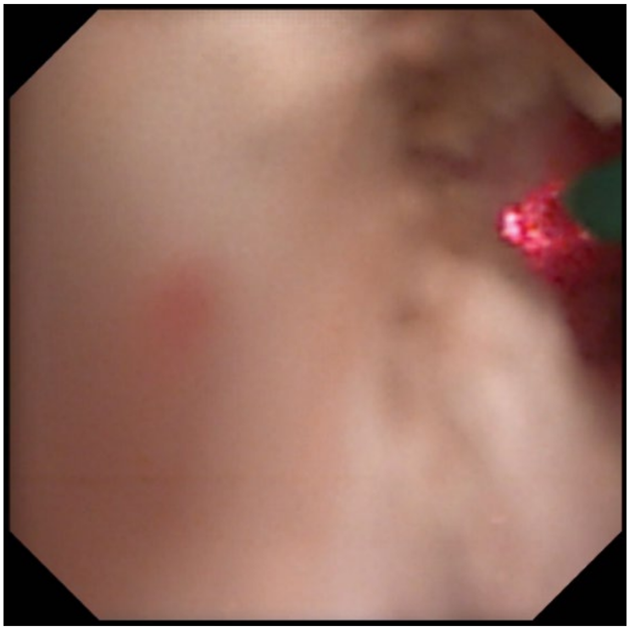

**Figure 54.8** View of incised stricture after first pass with the laser. Laser is positioned to start the second pass to deepen the incision.

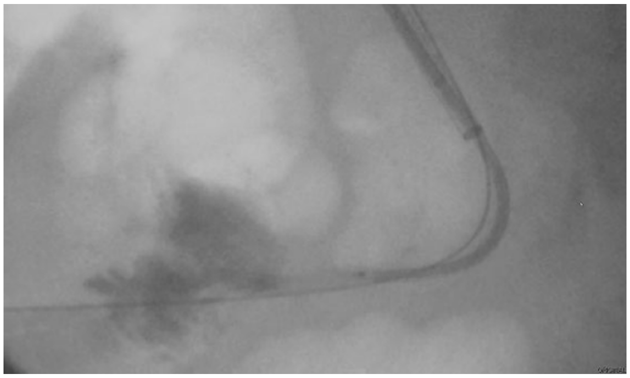

**Figure 54.9** Radiographic view of contrast media injection through ureteroscope resulting in extravasation, indicating full-thickness endoureterotomy.

## Post-treatment ureteral stenting

Regardless of the primary method used to treat UES, ureteral stenting is commonly employed to allow healing, limit extravasation of urine, and maintain patency. Ideal duration of stenting in the postoperative period is undefined, and four to six weeks may be reasonable. There is some evidence to suggest that prolonged stenting may be detrimental and lead to tissue overgrowth and fibrosis [27]. There is also disagreement as to the optimal stent diameter. Some recommend larger stents or even double stents, while others that argue an excessively large stent may induce ischemia and scarring [24, 32, 33].

Ureteral stents may be deployed either forward or retrograde in a through-and-thorough fashion over a guidewire with fluoroscopic assistance. Synthetic double-J stents are most commonly used. For patients with ileal conduits, a nephroureterostomy tube can be positioned in reverse fashion, with the distal pigtail in the renal pelvis and the proximal port in the urostomy bag [34].

For patients with severe comorbidities or those who do not want to attempt a definitive procedure, chronic ureteral stenting may be acceptable, despite the risk of encrustation, infection, and the need for frequent exchanges (every 3–6 months). This method is often successful in relieving obstruction but does not treat the underlying stricture.

To alleviate some of the problems with polymer stents, the use of metal stents has been investigated. Metal stents offer the benefits of resistance to compression and increased exchange interval [35]. Metal stents have been used previously in the setting of malignant obstruction with some success, but their use in benign stricture disease is controversial [36]. Their use in UES is even more limited. Many studies evaluate their use in the context of general ureteral obstructions, both benign and malignant, and report on only a handful of UES as a subgroup.

A variety of metal stents have been used: self expandable, balloon expandable, thermo-expandable shape memory, covered, and double pigtail stents [37]. Each type has its own manufacturer-provided deployment device and instructions. Many require dilation of the stricture before insertion. Details regarding the frequency of exchanges is device-specific. The following metal stents have been used primarily in ureteral strictures of both benign and extrinsic malignant obstructions, but have also been reported in UES in small numbers. There are few direct comparisons of these products in treatment of ureteral obstruction, and fewer in the setting of UES.

Resonance (Cook Medical, Bloomington, IN, USA) is made of a magnetic resonance imaging (MRI)-compatible nickel-cobalt-chromium-molybdenum alloy without a lumen and is similar in shape to a double-J stent. It is deployed through an 8 Fr sheath introducer. The Memokath 051 (Endotherapeutics, Epping, NSW, Australia) is a thermo-expandable shape memory stent made of nitinol and has a lumen. The stent is deployed over a guidewire with the provided sheath. The stent is then expanded *in situ* with the injection of normal saline at 65 °C [38]. The Allium URS stent (Allium Medical, Caesarea Industrial Park South, Israel) is a nickel-titanium alloy mesh invested with a biocompatible polymer to prevent tissue ingrowth and encrustation. It is available in two sizes, 30 and 24 Fr, and can be retrieved endoscopically. It is deployed over a guidewire in conjunction with the provided 10 Fr sheath [39]. The Uventa (TaeWoong Medical, Gyeonggi-do, South Korea) incorporates a triple-layer design consisting of a layer of PTFE between two nitinol layers in an expandable mesh capable of treating the entire length of the ureter. It is placed over a guidewire with a preloaded delivery system. The stent comes in 7, 8, and 10 Fr diameters.

## Novel techniques

Recently, there have been descriptions of novel endoscopic treatments of UES. These are typically technologies borrowed from other fields which have been adapted for experimental use in the ureter. Little or no comparative data exist, and publications have very limited follow-up.

In 2010, Boylu and associates reported use of a peripheral cutting balloon microsurgical dilator initially designed for use in coronary angioplasty. The balloon features four longitudinal microsurgical blades on a 2 cm-long balloon that dilates to 8 mm. In their study of only three patients with 12 month follow-up, improvement in hydronephrosis and serum creatinine were observed [40]. In 2007 Orsi and colleagues treated four UES with the Polar-Cath balloon dilator (Boston Scientific, Marlborough, MA, USA), requiring only one re-intervention during 12 months of follow-up [41].

## Surgical outcomes

The definition of success varies in the literature, but typically involves radiographic improvement in – or resolution of – obstruction, as well as absence of pain, infection, or stent, with recovery of normal activity.

### Balloon dilation

Balloon dilation is the oldest and most thoroughly evaluated endourologic treatment modality. Ten contemporary studies were reviewed comprising a total of 232 primary procedures. Success rates varied from 0 to 67% with a mean of approximately 22% [6, 18, 42–50] (Table 54.1). Follow-up ranged from 9 to 29 months. Larger contemporary series with mean follow-up of greater than 24 months demonstrate similar levels of success and reduced patency rates at longer-term follow-up [42]. There was great variability pertaining to balloon size, inflation pressure, time of inflation, and number of cycles needed to perform successful dilation. There was no standardization in the size of stent used postoperatively nor in the duration of stenting. When reported, stricture length was the parameter most predictive of treatment success or failure, with longer strictures having worse outcomes [6, 42, 43, 47].

## Endoureterotomy

Due to the poor outcome and long-term durability of balloon dilation, endoureterotomy has become the initial endoscopic treatment of choice [18]. Regardless of the energy source used, incision of the ureter, with or without concomitant balloon dilation, appears to be more effective than balloon dilation alone. In the 15 studies included in this review (Table 54.2), 215 individual procedures were captured. Success rates were reported between 33 and 100% (mean of 60%) with a follow-up ranging between 10 and 60 months [3, 7, 18, 19, 24, 28, 29, 42, 43, 50–58]. Studies of cold-knife incision were the least common, and the lack of new publications over the past several years indicates this technique has largely been abandoned. Wire-mounted cold-knife incision achieved a patency rate of 60.5% with 3 year follow-up in the largest and most recent study of this technique in 2003 [29].

Electrosurgical and holmium laser endoureterotomy are more commonly cited in the literature and have similar success rates (70 and 64%, respectively), although the former group had longer follow-up [3, 7, 18, 19, 28, 42, 56–58]. These techniques are advantageous because they allow direct visual inspection and incision of the ureter. Additionally, these modalities utilize instruments commonly used in other urologic procedures.

Acucise incision has demonstrated superiority to balloon dilation with a mean success rate of 35%, which is lower than the methods which use direct visualization [18, 24, 42, 52–55]. Head-to-head comparison of each modality is difficult. Even in the study by Schondorf and associates [42], in which patients underwent balloon dilation, Acucise, or holmium laser endoureterotomy, patients were not randomized and the choice of modality used was not explained. Despite this, as well as different patient numbers in each group, Acucise and holmium laser incision had similar success rates of 33%. Electroincision and cold-knife incision were not evaluated in this study.

As with balloon dilation, all procedures were concluded with stent placement, but no consensus on stent size (6–22 F) or duration (1.5–28 weeks) was noted. Six weeks was the most commonly cited duration of stenting [7, 19, 50, 52–54, 56]. When assessed, stricture length less than 1 cm and ipsilateral renal function greater than 25% were the strongest predictors of success. As would

be expected, some investigators demonstrated lower success rates for left-sided strictures.

## Chronic stenting as long-term management

Chronic stenting (Table 54.3) is most often utilized for patients who are too ill for definitive intervention, have a limited life expectancy, or wish to be less aggressive with treatment. Despite the use of chronic stenting in other ureteral obstructive processes, little data is available for its use in management of UES. Only one study reported long-term data for chronic stenting [44]. Success was only 45% at 26 months and periodic exchanges were necessary. Although stent exchange in patients with ileal conduits is not typically complicated, sometimes the altered anatomy can make exchanges difficult [59, 60].

Interest in metal stents is growing and several small studies have evaluated their use. Because of heterogeneity in metal stent designs, assessing them as a single group may not be appropriate. As described previously, there are a variety of metal stents (self-expandable, balloon expandable, thermo-expandable shape memory, covered, and double pigtail stents) for UES. The most studied are the Wallstent self-expandable stent (Boston Scientific), the Palmaz balloon-expandable stent (Palmaz Scientific, San Antonio, TX, USA) and the Resonance stent (Cook Medical). The Wallstent and other self-expandable stents are the best reported with 108 procedures. Overall success was 62% (range of 16.7–100%) [61–70]. However, most studies are small and have limited follow-up (6–39 months). In the single largest and most contemporary study of 56 procedures, success was 41.1% with mean follow-up of 39.2 months [61]. Balloon expandable stents such as the Palmaz stent have similarly reported success rates of 100%; however, this is in only three reported procedures with mean follow-up of 10.3 months [63, 65, 68, 71]. Resonance double-J metal stents were also reported; however, success was only 50% at a mean of 6.8 months [62]. Newer thermo-expandable shape memory stents like the Memokath 105 are being used, but both short- and long-term data are lacking [72, 73]. Clearly, more research with larger cohorts and longer follow-up is needed.

## Complications

Complications of endourologic management of UES include pyelonephritis, sepsis, and bleeding. In the most contemporary series of 96 interventions, there were a total of nine infectious complications [42]. Overall, balloon dilation had the fewest side effects and complications. Endoureterotomy is known to have increased risks compared to balloon dilation. The most serious complications involve vascular injury. In the series of 30 endoureterotomies of Wolf and colleagues, there was one reported laceration of the common iliac [24]. More recent series using direct visualization techniques do not report any serious bleeding complications [7, 19, 42]. Overall, it appears that as the techniques become more refined, the likelihood of complications decreases.

Complications related to stenting are primarily infection, encrustation, and obstruction [44]. Even use of metal stents has risks. Because of the heterogeneity of devices, it is again hard to group them as a whole. The resonance stent, most notably, was found to have a migration rate of 90% in one study [74], however most investigators have not encountered such a high incidence [62]. As many of the studies involving metal stents included strictures other than UES, complications specifically pertaining to UES are hard to ascertain. Based on the literature, there does appear to be a risk of tissue ingrowth [75]. Tables 54.1–54.3 summarize outcomes pertaining to complications of endoscopic management of UES.

## Postoperative follow-up

Due to the high failure rate of endourologic treatment methods, close monitoring is imperative. While there are no standard guidelines on surveillance schedules, follow-up should include serum chemistries to monitor electrolytes and renal function, and routine imaging to assess for hydronephrosis or stability of renal morphology [18, 19, 29, 57]. Because UES are rare and can present in a heterogeneous fashion, and because multiple endoscopic treatment modalities exist, surveillance needs to be tailored to individual patients. Many UES patients will have a history of urothelial carcinoma and will be monitored routinely for recurrence of malignancy with computed tomography, which can also serve to monitor for return of UES. A reasonable follow-up protocol for UES may include serum chemistries as well as periodic imaging with ultrasound at intervals beginning at 3 months and increasing at the clinician's discretion. Any suggestion of recurrent obstruction, such as flank or abdominal pain, pyelonephritis, rising serum creatinine, or worsening hydronephrosis on imaging, should prompt a renewed investigation into the cause, using the same methods as described for initial evaluation.

## Conclusion

UES are a relatively uncommon but difficult to manage complication of urinary diversion. At this time, there are few if any definitive technical considerations at time of anastomosis to eliminate the risk of strictures. Initial management remains a dilemma, and advances in endoscopic technology have led to a variety of approaches. Despite inferior long-term success compared to open repair, endoscopic treatment remains a reasonable first-line approach in appropriately selected patients, and does not seem to greatly complicate matters should later open surgical revision become necessary. Balloon dilation is the safest and most easily accomplished procedure, but has disappointing durability. Endoureterotomy, with or without concomitant dilation, seems to have become the minimally invasive treatment of choice regardless of incision method, but has a slightly increased risk of complications. Generally, success is more likely in patients with right-sided strictures and satisfactory ipsilateral renal function. Stricture length less than 1 cm also appears to be a significant factor predicting success. Long-term stenting still remains a viable option for those willing to undergo periodic exchanges, and refinement of metal stent technology may lead to additional therapeutic choices. Since UES are relatively rare and tend to be treated at tertiary referral centers, an international collaborative registry gathering data on large numbers of patients may be the only rigorous way to evaluate these methods and advance techniques and outcomes.

# Ureterorenoscopy: Ureteral Stents and Postoperative Care

*Ben H. Chew, Anthony Emmott, Dirk Lange, & Ryan F. Paterson*

*Department of Urologic Sciences, University of British Columbia, Vancouver, BC, Canada*

Ureteroscopy is commonly used to treat urolithiasis and has become a standard endoscopic technique replacing open stone surgery of the past. This chapter will discuss analgesia and other medications utilized in the postoperative period. The use of ureteral stents and new and future technologies will also be discussed. Finally, the use of postoperative imaging following ureteroscopy will be examined.

## Ureteroscopy: outpatient versus inpatient management

The overwhelming majority of patients undergoing flexible or semirigid ureteroscopy and intracorporeal lithotripsy are treated on an outpatient basis. Common indications for unplanned admission postprocedure include flank or bladder pain not manageable with oral analgesics, fever, urinary retention, or significant hematuria. In addition, management of the uncommon procedural complications of ureteral perforation or avulsion account for a small percentage of admissions. In common with other planned outpatient procedures, late procedure start times and social circumstances precluding early discharge may result in overnight admission [1]. Box 55.1 lists techniques to increase the likelihood of maintaining ureteroscopy as an outpatient procedure. Emergency admission for renal colic with subsequent emergent ureteroscopy can increase the likelihood of ongoing hospital stay postprocedure [1].

## Prescriptions

Following any surgery, physicians typically prescribe medications for the postoperative period consisting of an antibiotic and/or analgesic. Following ureteroscopy, there are many types of analgesics that can be prescribed and there is very little evidence for antibiotics in the postoperative period. In addition, there are two other types of medication that can be prescribed to patients with urolithiasis. In the case of uric acid stones, patients may be prescribed a urinary alkalinizing agent to dissolve any remaining fragments. The second are alpha-antagonists which have been utilized to facilitate passage of fragments by relaxing ureteral smooth muscle [2, 3] and to help alleviate postoperative ureteral stent symptoms [4–7].

### Antibiotics

Patients are often prescribed antibiotics following surgical cases to prevent infection. The decision on whether to prescribe antibiotics should balance the risk of infection with the risk of adverse effects of antibiotics and the induction of antibiotic-resistant bacterial strains. In cases where the risk of infection is high, the risk of complications such as *Clostridium difficile* colitis and inducing bacterial resistance is justified. In cases where there is a low risk of infection, then the utility of postoperative antibiotic prophylaxis becomes less clear.

There is good evidence to give antibiotics at the time of surgery. A randomized trial of 113 patients were administered either levofloxacin 250 mg by mouth 60 minutes prior to ureteroscopy or no antibiotics [8]. The rate of bacteriuria in the control group was 12.5% compared to 1.8% in those receiving levofloxacin. They did not examine the use of antibiotics in the postoperative period.

The current American Urological Association guidelines (2016) recommend preoperative antibiotic prophylaxis in all patients undergoing ureteroscopy administered within 60 minutes of the start of surgery. It can be a single oral or intravenous dose of antibiotic that covers

**Box 55.1 Technique to increase likelihood of outpatient ureteroscopy.**

1) Thorough discussion with patient and family preoperatively regarding postureteroscopy clinical course and expectations
2) Operative start time during morning or early afternoon
3) Prompt surgical intervention in patients presenting emergently with renal colic
4) Dose of nonsteroidal anti-inflammatory drug such as Ketorolac at completion of procedure
5) Bladder drainage at completion of procedure
6) Avoidance of routine ureteral stenting for uncomplicated ureteroscopy
7) Appropriate stent length and diameter
8) Consideration of anticholinergic medications for stent-related bladder spasms
9) Consideration of alpha-blocker medication for stent discomfort

both Gram-positive and Gram-negative uropathogens. Local antibiograms should be consulted for selecting an appropriate antibiotic to prevent antimicrobial resistance and ensure the best patient outcomes. There is no good evidence in the literature for using antibiotic prophylaxis in the postoperative period.

## Analgesics

### Analgesics for renal colic and passage of fragments

The options for treating postoperative pain range from the commonly used analgesics which target pain at the central nervous system to medications that target specific receptors in the urothelium. The literature is lacking in suggestions for analgesics specifically after ureteroscopy, but the passage of fragments after intracorporeal lithotripsy can be accompanied with pain very similar to that found in renal colic.

### Alpha-antagonists for stone expulsion

Alpha-antagonists inhibit smooth muscle contraction and have been used extensively in the treatment of benign prostatic hyperplasia. In the endourological world, they have found two further purposes: as medical therapy to facilitate stone expulsion and to relieve ureteral stent symptoms. The theory underlying these observations is relaxation of ureteral smooth muscle to allow ureteral stones to pass and, in the case of stents, to prevent ureteral spasm. This is done by inhibiting selective alpha$_1$-adrenergic receptors and reducing ureteral contractility [9, 10].

Medical expulsive therapy has been found to increase the stone passage rate as well as hasten the time to stone passage and reduce pain, narcotic requirement, and hospitalizations for renal colic [11, 12]. A Cochrane systematic review of 32 studies (5864 participants) found significantly higher stone-free rates in the alpha-blocker group compared to standard therapy (risk ratio 1.48, 95% confidence interval [CI] 1.33–1.64). Reductions were found in stone-expulsion time, number of pain episodes, need for analgesic medication, and hospitalization with alpha-blockers. However, patients experienced more adverse effects with alpha-blocker therapy than standard therapy or placebo [13]. Another meta-analysis evaluating 693 pooled patients found a greater likelihood of stone passage than those given placebo when given an alpha-blocker or calcium channel blocker with steroids [3]. The number needed to treat in this analysis was only four, indicating that this is a worthwhile and effective treatment for ureteral stones. Some studies have produced an even higher rate of stone expulsion in patients administered tamsulosin [14].

A more recent large, multicenter clinical trial randomized 1167 patients with a single ureteral stone 10 mm or less to tamsulosin, a calcium channel blocker (nifedipine), or placebo [15]. The primary end point was need for intervention by 4 weeks after randomization. Participants, clinicians, and trial personnel were blinded to treatment assignment. There was no difference in stone passage rates between tamsulosin, nifedipine, or placebo groups, as 80–81% of patients did not need further intervention in all three groups. No differences were found between the trial groups for visual analogue pain scores at 4 weeks, number of days of analgesic use, or time to stone passage. Criticisms of this study include the fact that the need for surgery was used as a surrogate end point rather than radiologic testing. Additionally, since more than 75% of the stones were 5 mm or less, one could argue that these stones were likely going to spontaneously pass anyway and that the alpha-blockers were unable to show a difference.

### Analgesics for stent-related pain

Phenazopyridine and oxybutynin have been administered orally in an attempt to relieve stent-related symptoms. A randomized trial involving 60 patients randomized to phenazopyridine, oxybutynin, or placebo was performed and the following measures were recorded: narcotic use, flank pain, suprapubic pain, urinary frequency, urgency, dysuria, and hematuria [16]. There was a trend, although statistically insignificant due to the small group numbers, for a reduction in narcotic usage in the oxybutynin group. Phenazopyridine significantly reduced the amount of hematuria patients had on postoperative day 1 compared to placebo. Perhaps a larger study would discern if either of these medications would be helpful in relieving stent symptoms. A meta-analysis of 1408 patients showed reduction in stent-related symptoms, as measured by the International Prostate Symptom Score, visual analogue pain scale, and quality of life instruments, for alpha-blockers (alfuzosin or tamsulosin) alone and antimuscarinics (tolterodine or solifenacin) alone compared to control. The combination of alpha-blockers and antimuscarinics provided even greater reduction in stent-related symptoms [17].

#### Alpha-blockers and stent-related pain

Patients randomized to alfuzosin following ureteroscopy and stent insertion had significantly less narcotic use, less overall pain in the back and groin area, less flank pain during urination, and less urinary frequency compared to patients given placebo [18]. Tamsulosin also produced similar significant results in other placebo-controlled prospective trials of patients undergoing ureteral stent placement following ureteroscopy [4, 7, 19]. In a network meta-analysis, tamsulosin and alfuzosin were shown to have significant reduction in the urinary symptom scores and body pain scores of the Ureteric Stent Symptoms Questionnaire when compared to placebo. However, no significant difference was found between tamsulosin and alfuzosin with respect to these measures [20]. It would appear that alpha-blockers administered postureteral stent insertion is an excellent way to prevent and relieve symptoms.

### To stent or not to stent? That is the question

The decision must be made at the end of each ureteroscopy on whether or not a ureteral stent should be placed. The absolute indications to leave a ureteral stent are listed in Box 55.2 [21]. The evidence on whether to stent a patient following ureteroscopy is controversial. There is good evidence from randomized clinical trials suggesting that patients without ureteral stents experience fewer symptoms than those who receive a ureteral stent [1, 22–25]. In unstented patients postureteroscopy, few patients require surgical intervention for ureteral obstruction with the majority managed by improved pain control. In addition, the vast majority of patients treated on a "stent-less" basis have no obvious preprocedure predictor of subsequent flank pain or obstruction. Although the avoidance of a postprocedure ureteral stricture is commonly encountered in the literature as a justification for ureteral stenting, the meta-analysis of randomized controlled trials by Nabi et al. indicates no difference in stricture rate between those stented and nonstented [26].

**Box 55.2 Indications for ureteral stenting postureteroscopy [21].**

1) Ureteral perforation intraoperatively
2) Ureteral dilation greater than 10 Fr (either coaxial or balloon dilator)
3) Significant ureteral edema due to stone (e.g. impacted stone)
4) Failure to advance the ureteroscope due to a narrow ureter or ureteral orifice and in preparation for a subsequent ureteroscopy after 7 days
5) Infected urinary system with an obstructing system
6) Large stone burden with many fragments remaining to pass
7) Solitary kidney

Supporting the role of postprocedure ureteral stenting is the study by Borboroglu et al. in which the authors reported a risk for admission for flank pain postureteroscopy of 7.4% in the unstented group versus a 0% re-admission rate in the stented group [27]. However, the overall cohort of unstented patients had substantially less flank pain. While some studies have shown fewer symptoms and less pain in those patients without a stent, a metaanalysis found a trend towards fewer urologic complications in patients who received a stent following ureteroscopy [28]. Some of the trials included in this analysis did not find a difference in complication rates between stented and unstented patients, but there was an overall 4.5% reduction in rate of complications in those patients who underwent placement of a stent following ureteroscopy ($P = 0.001$, 95% CI 1.8–7.3%). When a more stringent random effects model was applied, however, this difference was not statistically significant (4.1% risk difference, 95% CI 1.8%–10.1%, $P = 0.175$). At present in the literature, there is no significant difference in outcomes between patients who receive a ureteral stent compared to those who do not receive a ureteral stent following ureteroscopy.

When a ureteral access sheath is used during ureteroscopy, there is good evidence to place a stent afterwards. A retrospective comparison of 51 patients stented and 51 patients not stented after flexible ureteroscopy with a ureteral access sheath found that stented patients had significantly lower postoperative pain scores and were less likely to seek medical attention for pain compared to unstented patients [29]. In another retrospective review, the rate of return to the emergency department of nonstented patients after ureteroscopy was significantly higher in those who had a ureteral access sheath (37%) compared to those treated without a ureteral access sheath (14%) ($P = 0.04$) [30].

## Which stent is most comfortable?

Once a decision to place a stent is made, the question becomes which stent to use. There are no conclusive data as to which commercially available stent is the most comfortable for patients. There are a variety of factors that are taken into consideration including the softness (durometer) of the stent, its design, and its size both in length and diameter.

Intuitively, one would think that softer stents would be more comfortable than harder stents; however, randomized trials have shown no difference between soft and hard stents in terms of urinary symptoms, pain, time away from work, or sexual dysfunction utilizing the Ureteral Stent Symptom Questionnaire (USSQ) [31], the only validated tool for evaluating ureteral stent symptoms [32, 33]. In one trial, patients randomized to a "stiffer" stent that was greater than 64A durometer in stiffness (Percuflex® stent; Boston Scientific, Natick, MA, USA) were compared to patients who received a softer stent of less than 64A (Contour™ stent, Boston Scientific) [32]. No differences between groups were seen at 1 and 4 weeks in terms of urinary symptoms, overall body pain, work performance, or general health index. Lennon et al. randomized patients to firm polyurethane stents or a softer Sof-Flex™ stent [33]. Patients with firmer stents had a higher rate of dysuria, and renal and suprapubic pain; however, there was no significant difference in the degree of bladder inflammation, stent encrustation, urgency, frequency, nocturia, or hematuria. The only shortcoming of this study is that patients were not evaluated with a validated stent symptom questionnaire, the USSQ.

More recently, Lingeman et al. and the Comfort Study Team utilized the USSQ to assess whether patient comfort was best in a short loop tail stent, a long loop tail stent, or a Percuflex Plus stent (Boston Scientific) or Polaris stent (Boston Scientific) [34]. All kidney curls were identically composed of a 6 Fr pigtail curl and the Percuflex Plus stent consists of the same material and coil in the bladder end. The distal ends differed in the other three stents: the short loop tail stent (5 cm long, 3 Fr diameter) and long loop tail stent (8 cm long, 3 Fr diameter) consisted of two loops and the Polaris stent was a dual durometer stent with a stiffer renal curl to prevent migration but a softer curl in the bladder in an attempt to decrease bladder irritation and symptoms. The 236 patients were randomized to receiving one of the stents following uncomplicated ureteroscopy and were administered the USSQ at baseline, 4 days after stent placement, and 5 days after stent removal. There were no statistically significant differences in pain scores between any of the stent groups. There was decreased use of narcotics in the first 1–3 days after stent placement in the short loop tail stents, but this was insignificant at 4 days. Most notably, the USSQ may not have been administered at the correct time as all patients had the most severe discomfort symptoms on postoperative day 1. By day 4, all symptoms had subsided when the USSQ was administered, thus there may have been a significant difference if it was measured at day 1. It also goes to support the theory that stent symptoms occur from irritation of the trigone of the bladder. Having softer material that also has less mass in the bladder may help alleviate ureteral stent-related symptoms.

## Stent length relating to discomfort

Even though there are no clear data to support the use of one type of stent over another, there are good data that longer stents that protrude into the bladder produce more symptoms. Choosing the correct length of stent will significantly reduce patient stent symptoms. Stents that cross the midline of the bladder result in significantly more dysuria, urgency, and irritative voiding symptoms and more impaired quality of life than stents that do not cross the midline [35, 36]. Giannarini et al. found significant association between the distal stent loop crossing the midline of the bladder and the urinary symptoms, body pain, general health, work performance, and sexual matters domains of the USSQ [37]. Long stents are associated with excess material in the bladder – and, therefore, presumably with more bladder irritation – but do not result in excess stent length in the kidney [35]. Fluoroscopic studies of stented patients show that, with motion, the stent tends to bow in the mid and proximal ureter and the excess length slides in and out of the bladder at the ureterovesical junction, with relatively little motion seen in the kidney [38]. Flank pain was not affected by stent length, but there is good evidence that negative bladder symptoms are increased in patients with longer stents compared with those who are stented with the correct length stent.

However, more recent studies have not been able to consistently support the association between excess stent length and urinary symptoms. In one study, patients completed the USSQ before stent removal and were categorized by X-ray into three groups with contralateral, tangential, or ipsilateral stent position. While the ipsilateral stent group showed lower USSQ scores, these differences were not statistically significant between groups for the USSQ total score ($P = 0.35$) and subgroup scores [39]. A multicenter randomized trial between multilength 6 Fr × 22–30 cm Contour VL and 6 Fr × 24 cm Contour ureteric stents also found no significant difference in the same USSQ subgroup scores, adding ambiguity to the question of whether excess stent material in the bladder adds to stent-related symptoms [40].

How is the correct stent length chosen? This question has baffled many a urologist and numerous methods have been described including measuring patient height, torso length, intravenous urography, and direct ureteral measurement. One study found that direct intraoperative measurement of ureteral length was better than patient height at correlating with the correct stent length [41]. Another study evaluated several anthropometric factors, including patient height, body mass index, and distances from the acromion process (shoulder) to the head of the ulna (wrist), olecranon process (elbow) to the head of the ulna, xiphoid process to pubis, umbilicus to pubis, and anterior iliac spine to anterior iliac spine [42]. They measured ureteral length intraoperatively with a 5 Fr ureteral catheter and found that height, xiphoid process to pubis distance, and the shoulder to wrist distance all correlated with ureteric length. Ho et al. recommend a 22 cm stent for patients 149.5–178.5 cm in height, but did not study patients outside this height range [36]. To date, there is no standard accepted method of determining the most appropriate length of ureteral stent.

## Stent coatings

In an effort to reduce bacterial infection related to indwelling material, antimicrobial peptides have been proposed to reduce bacterial adhesion and biofilm formation, thus preventing infection. Antimicrobial peptides have been shown to substantially improve the infection resistance of biomaterial surfaces using polymer brushes to increase the density of the antimicrobial peptides [43]. Antimicrobial activity was observed for both Gram-positive and Gram-negative organisms. Antimicrobial peptides may be used in the future to reduce systemic antibiotic administration for ureteral stent-related infections and thus prevent the induction of antibiotic resistance.

## Biodegradable ureteral stents

Ureteral stents typically require a secondary procedure for removal if a suture tether is not used. This can add cost, inconvenience, and patient discomfort. In addition, if a patient is lost to follow-up and if there is any miscommunication about the patient having a stent, a "forgotten" stent may result, potentially requiring several surgeries for removal or even loss of the renal unit [44–46]. There have been case reports of mortality stemming from forgotten ureteral stents [47]. Attempts to reduce retained stents have included a stent registry [48, 49]. A stent without a suture tether that does not require cystoscopic removal has also been developed using a high-powered magnet catheter that is inserted into the bladder to bind a steel bead attached to the distal end of the stent for removal [50]. This low-cost alternative to cystoscopy offers a safe "blind" removal of the ureteral stent in any type of setting under local anesthetic.

Perhaps the holy grail of preventing a retained stent is one that would degrade over time. The ideal biodegradable stent must function to provide drainage like a plastic stent, be easy to deploy, be radiopaque, and maintain its integrity for at least a certain amount of time in order for ureteral edema etc. to subside, but not overstay its welcome and take too long to degrade. Furthermore, it should be comfortable, biocompatible to surrounding tissues, and degrade in a fashion that does not obstruct the distal ureter.

Lingeman et al. performed a phase I clinical trial to evaluate the Temporary Ureteral Drainage Stent (TUDS, Boston Scientific) in 18 patients [51]. All stent material was extruded within 4 weeks with only one stent prematurely migrating into the bladder at day 1. A phase II trial of the TUDS stent evaluated 88 patients following ureteroscopy and the stents were eliminated from the ureter at a median time of 8 days and eliminated completely from the body at a median of 15 days [52]. By 30 days, 84% (74/88) of the stents had completely degraded. Unfortunately, three patients retained stent fragments at 3 months and required surgical intervention for removal. For the majority of patients (78.2%), the stent was effective at providing upper tract drainage for at least 48 hours postoperatively: the targeted time to define success. Due to the manufacturer's concerns about retained fragments, the TUDS stent is no longer commercially available.

A more recent degradable stent composed of ʟ-lactide, glycolide, and copolyester components similar to those found in absorbable sutures has been developed and tested in a porcine model (Uriprene™, Poly-Med, Greenville, SC, USA) [53]. It has been developed to degrade within 2–3 weeks with 90% of stents being completely eliminated from the body by week 4 in a porcine model [54], with one pig retaining three small fragments less than 1.5 cm in the bladder. The biodegradable stent was biocompatible on histology, with fewer abnormal histological findings, and resulted in significantly less hydronephrosis in comparison to the control biostable stents. Drainage was equivalent to control stents as seen by excretory urogram. The safety of this stent has been tested and proven in animal model of ureteral stenting. Human trials will determine its true degradation time and if there is any improvement in comfort. Hopefully, the development of biodegradable stents will aid in reducing stent symptoms and infection, and avoiding the forgotten stent syndrome.

## Postoperative imaging following ureteroscopy

Routine imaging postoperatively remains controversial despite over a decade of studies reported in the era of small-diameter semirigid and flexible ureteroscopes. Multiple authors, in the setting of either a randomized controlled trial of stented versus unstented ureteroscopy, or as a retrospective case series, have demonstrated a low risk of postureteroscopy obstruction [22, 55–69] (Table 55.1).

Given the high stone-free rate for ureteroscopy of upper tract calculi, the major indication for postprocedure imaging is the detection of a ureteral stricture, with a risk in uncomplicated cases of less than 5%. Predisposing factors for ureteral stricture postureteroscopy include preoperative factors such as chronic stone impaction, reduced renal function, coexistent ureteral stricture on the treated side, and complete ureteral obstruction [65, 70, 71]. In addition, intraoperative factors such as significant ureteral edema, ureteral trauma, or ureteral perforation are established risk factors for ureteral stricture and mandate close long-term radiologic follow-up [70, 71]. Indeed, the retrospective case series of Roberts et al. [71] reported a 24% incidence of ureteral stricture in patients with chronic ureteral stone impaction greater

Numbers of patients, where reported, consists of patients with upper tract urolithiasis undergoing ureteroscopic intervention. R, semirigid ureteroscope; F, flexible ureteroscope; US, ultrasound; CT, computed tomography; IVP, intravenous pyelography; IVU, intravenous urogram; KUB, kidney–ureter–bladder; NCCT, noncontrast computerized tomography.

than 2 months. However, previous iatrogenic ureteral perforation from previous stone manipulation was encountered in the majority of stricture cases. Regardless, the more contemporary series of Beiko et al. [70] reported that all four cases of ureteral stricture postureteroscopy occurred in patients with risk factors.

Adiyat et al. [65] retrospectively compared the incidence of ureteral stricture between a high-risk group of complicated ureteroscopy cases ($n = 56$) compared to a cohort of uncomplicated ureteroscopy patients undergoing routine stone surveillance imaging ($n = 158$) (Table 55.1). In common with other authors, complicated ureteroscopy, consisting of cases with encountered impacted stone, need for ureteral balloon dilation, or ureteral perforation, demonstrated a substantial risk of ureteral stricture of 5.3%. In contrast, long-term radiologic surveillance in the uncomplicated ureteroscopy group (mean follow-up of 10.2 months) revealed no ureteral strictures. This evidence further supports selective imaging in patients with known risk factors for postoperative ureteral stricture development. The predisposition of a ureteral stricture from ureteral balloon dilation remains controversial with some authors suggesting this a risk factor [65, 70] while others do not [1, 68]. In one study, the rate of stricture in patients who underwent ureteral balloon dilation was 1 in 107 patients reviewed (0.9%) [72].

Multiple authors advocating limited radiologic evaluation in the early postureteroscopy period have based this recommendation on the presence or absence of pain as an indication for imaging [62]. The majority of studies assessing the etiology of pain after ureteroscopy demonstrate a substantially greater likelihood of a retained stone fragment rather than a stricture being responsible [65, 73]. Barbour and Raman [68] studied 324 patients following ureteroscopy and found a 48-fold greater risk of abnormal imaging postureteroscopy for patients with symptomatic presentation. They also found that of those with symptomatic presentation and hydronephrosis on subsequent imaging, 43% were due to ureteral obstructing residual fragments and thus recommend directly proceeding to stone protocol CT for symptomatic patients. Other factors that were found to increase risk of abnormal imaging included larger stone size (5 mm increments, odds ratio 5.1, $P = 0.008$), longer operation duration (30 minute increments, odds ratio 1.01, $P = 0.001$), and prior ipsilateral ureteroscopy, and thus a CT or renal ultrasound was recommended for this population. Bugg et al. [73], as advocates of limited postureteroscopy imaging, reviewed the chance of postoperative obstruction when pre-operative obstruction and postoperative pain are combined. The authors reported that patients with preoperative obstruction and postoperative pain had a 67% chance of having residual fragments and a 50% chance of residual obstruction. In contrast, 96% of patients without preoperative obstruction and no postoperative pain had no persistent obstruction or residual fragments. However, the risk of missing silent obstruction remains as 25% of asymptomatic patients had residual stone fragments or obstruction.

The correlation of pain with postureteroscopy ureteral obstruction has been questioned by Weizer et al. [57], who caution urologists regarding the risk of silent hydronephrosis. In this retrospective case series, the absence of pain was noted in seven patients who presented postoperatively with silent hydronephrosis out of a total 241 patients. This translates into a 3% risk of renal functional impairment in patients undergoing ureteroscopy if relying on only symptoms to prompt imaging. Similarly, Manger et al. [64], in a retrospective case series of 289 patients with available postureteroscopy sonography, reported that 27 (9.3%) had sonographic evidence of hydronephrosis (14 asymptomatic). From this series, the risk of silent obstruction is significant (4.8%), with the number needed to diagnose of 18 asymptomatic patients postureteroscopy to diagnose one case of hydronephrosis. Further, the negative predictive value and positive predictive value of ipsilateral flank pain for hydronephrosis were 94 and 35%, respectively. In conflict with this large percentage of patients with postureteroscopy hydronephrosis (providing evidence for routine postureteroscopy imaging) is the small number of patients in this series with asymptomatic hydronephrosis who eventually required surgical intervention.

Sutherland et al. [74] compared the economic costs of routine imaging after ureteroscopy with selective imaging in only symptomatic patients after ureteroscopy. They considered the costs of complications following ureteroscopy, including postoperative pain, stricture, and silent obstruction with subsequent renal loss due to silent obstruction causing chronic kidney disease, end-stage renal disease, and cardiovascular disease. Taking these complications into account and assuming a rate of silent obstruction of 1.9%, the authors found the cost of ureteroscopy with routine postoperative imaging to be US$5326 per patient whereas with selective imaging it was $5196 per patient. Despite a modest $130 cost savings per patient under a selective imaging model, Sutherland et al. recommended routine postureteroscopy imaging to offset the patient risk of loss of kidney function due to silent obstruction.

The majority of studies assessing imaging postureteroscopy have relied on intravenous pyelography or CT scans to rule out obstruction. In contrast, Manger et al. [64] demonstrate the value of renal ultrasound postureteroscopy as a screening study. Given the increasing recommendations to limit medical radiation exposure in our urology patients [75, 76], combined with ready availability of sonography, the authors recommend renal ultrasound as the imaging study of choice postureteroscopy in asymptomatic patients to rule out obstruction.

## Residual fragments after ureteroscopy

The management of residual stone fragments after urologic stone procedures is controversial. These stone fragments have the potential to grow, cause obstruction or infection, and contribute to recurring stone episodes. A retrospective study from six centers in North America of 232 patients with residual stone fragments found a 44% rate of stone-related complications, with 15% not requiring intervention and 29% requiring intervention [77]. Stone fragments greater than 4 mm were more likely to grow ($p < 0.001$), cause complications ($P = 0.039$), and require re-intervention ($P = 0.01$). The authors suggest pre-emptive treatment of residual fragments greater than 4 mm to prevent complications based on these findings.

## Summary

Postoperative use of ureteral stents is not supported for every routine, uncomplicated ureteroscopy. If a stent is to be left, however, the proper length stent should be inserted to reduce stent symptoms. Ketorolac, oxybutynin, or an alpha-antagonist may help reduce stent-related symptoms. Alpha-antagonists may also be prescribed postoperatively in an attempt to facilitate spontaneous expulsion of stone fragments. Postoperative imaging following ureteroscopy remains controversial following uncomplicated cases.

[2] *UCSD Comprehensive Kidney Stone Center, Department of Urology, University of California San Diego Health, San Diego, CA, USA*

## Introduction

Miniaturization of instruments, improved technique, and developing safety principles have led to ureteroscopy (URS) being a safe, effective option for stone therapy. With smaller-diameter ureteroscopes, less traumatic tips, and improved techniques, iatrogenic complications have declined and are now less common. To avoid intraoperative complications from URS, the surgeon should be familiar with the various complications, their incidence, associations, and the appropriate treatment. We review the various complications associated with URS and the strategies for safe URS.

## Classification

The definition and reporting of complications varies widely. Commonly employed reporting systems segregate complications either by severity (minor and major) or by chronology (intraoperative and postoperative). No standardized classification has been adopted specifically for endoscopic complications. Many investigators utilize the Clavien-Dindo classification; however, this system struggles to correlate the particulars of endoscopy. The Satava classification system attempted to address this deficit, with complications predicated on the intensity of management (Table 56.1) [1]. Several grading systems have emerged that are specific to the severity of ureteral wall injuries, which will be discussed later.

## Intraoperative complications

The incidence of intraoperative ureteroscopic complications ranges from 0.5 to 20%, with 1.5–5% being major complications [2]. The majority of complications are minor and managed conservatively.

### Bladder distention

Intraoperative overdistention of the bladder can lead to postoperative urinary retention and, on rare occasions, bladder perforation. Surgeons should note prostatic enlargement and pre-existing outlet obstruction as contributing factors to postoperative retention. A small-caliber Foley or red rubber catheter may be placed alongside the ureteroscope for bladder drainage. Monitoring bladder volume is particularly important for longer procedures performed without a ureteral access sheath (UAS). UAS use can mitigate this concern by creating a continuous irrigation flow system and bypassing the bladder.

### Failure to access the upper tract

Accessing the ureter or kidney can be difficult. Failure to access the upper tract has been reported at 1.6–1.8% with flexible URS and up to 8% with semirigid ureteroscopy [1, 3, 4]. Associated risk factors are stones >15 mm and proximal stones [4]; anatomic features also contributing to operative difficulty include patient body habitus, intrinsic or extrinsic ureteral narrowing, stone impaction, ureteral edema or lesions (iatrogenic or pathologic),

**Table 56.1** Clavien-Dindo and Modified Sativa classification systems for surgical complications.

| Clavien-Dindo | Satava, Modified |
|---|---|
| Grade I: any deviation from normal postoperative course | Grade 1: incidents without consequences for the patient |
| Grade II: requiring pharmacologic therapy with drugs other than those allowed in Grade I | Grade 2a: managed intraoperatively with endoscopic maneuvers<br>Grade 2b: managed with retreatment (additional surgery) endoscopically |
| Grade III: requiring surgical, endoscopic, or radiological intervention:<br>a) without general anesthesia<br>b) requiring general anesthesia | Grade 3: managed with open surgery or laparoscopy |
| Grade IV: life-threatening complication requiring intensive/critical care management:<br>a) single organ failure<br>b) multiple organ failure | |
| Grade V: death<br>Suffix “d” may be added for disability, indicating follow-up is needed after discharge to fully evaluate the complication | |

or genitourinary anatomy. Specific genitourinary anatomy that contributes to difficulty includes a cystocele, enlarged prostate, large intravesical median lobe, generalized edema, trabeculations, cellules, and abnormalities related to the ureteral orifice location, such as re-implanted, ectopic, or duplicated ureters. Perhaps the safest option for the management of failed access is to abort the procedure with ureteral stenting if possible.

## Techniques for difficult ureteral access

### Tight ureteral orifice

Numerous difficulties can arise when attempting to access the ureteral orifice. Several techniques exist for orifice identification or cannulation. These include telescoping the wire through a ureteral catheter to improve direction and stability, converting to a straight or curved hydrophilic wire, emptying/filling the bladder, and manually reducing a cystocele or vaginal prolapse (e.g. vaginal packing). Ancillary instruments for complex access include a ureteroscope, flexible cystoscope, Albarran bridge with 70° lens, or specialty ureteral catheters (Figure 56.1). In the absence of complete ureteral obstruction, Methylene blue or Fluorescein can be administered intravenously to endoscopically visualize the effluxing ureteral orifice, and intravenous contrast can illuminate the distal ureter radiographically. Furosemide administration will expedite this process.

If the ureteral orifice is narrow or stenotic, it may not accommodate the ureteroscope. Dilation may be accomplished with tapered dilators or dilating balloons. Such dilation can be associated with perforation, stone extrusion, and avulsion [5]. To prevent such injury from unknown ureteral anatomy or ureteral stone, the ureter should be visualized using retrograde pyelography before dilating maneuvers. Prestenting the ureter (staged approach) is also an option.

#### Difficult ureter

If difficulty is encountered passing a wire, several techniques may be employed. Retrograde ureterography can opacify the challenging anatomy and guide maneuvers. Telescoping the wire through a ureteral catheter and/or converting wires (e.g. combination polytetrafluoroethylene (PTFE)/hydrophilic wire, straight or curved hydrophilic wire) may be beneficial. If an obstruction or impacted stone is present, lubricating lidocaine jelly can be injected through a ureteral catheter positioned 1–2 cm beneath the stone/obstruction in an attempt to relax the ureteral smooth muscle and create separation between the stone and ureteral wall. To fluoroscopically visualize this maneuver, contrast agent can be mixed into the jelly. However, excessive injection force/pressure may injure the ureter, producing extravasation. Lastly, URS can be performed to endoscopically visualize the difficult ureteral segment and advance the wire under direct vision.

If wire access is achieved but URS remains difficult, entering a narrow ureteral orifice and negotiating a difficult ureter can be accomplished using two wires (safety and working wire) and by maintaining maximal distance between the wires opening the ureter to “shoehorn” the scope (railroad technique). The scope should be rotated, as needed, to maintain scope orientation between the wires.

If a stricture is encountered distal to a stone, it may be tapered or balloon-dilated followed by case resumption. If the stricture is incised, a stent should be placed with stone treatment later to prevent stone fragments migrating into the disrupted ureteral wall. When deciding between the two techniques, the surgeon should note that balloon dilation provides faster, less forceful access through a narrowed ureter [6]. Because ureteroscopes have decreased in size, incidence of balloon dilation has decreased; however, UAS utilization has been reported to increase balloon dilation use [7]. Failure to advance UAS after balloon dilation is rare but merits termination of case and stenting [7]. Repeat URS can be performed 1–2 weeks later. An antegrade approach remains an option should retrograde fail.

### Equipment failure

Equipment failure can preclude ureteroscopic success, with procedure abortion reported at a suspected underestimated 0.8% [1], while scope failure necessitating repair can be expected every 9–50 cases [8–11]. Most ureteroscope damage is iatrogenic, such as improper handling during instrumentation [12]. Most commonly, damage occurs to the working channel, especially the distal tip. The primary mechanism is passing instruments with the scope deflected or firing the laser within the scope’s working channel. The use of lithotrite alone predicts ureteroscope damage [12]. A major risk from laser use in a maximally deflected scope is damage to the channel at the point of maximum deflection due to energy released through microfractures in the quartz core material [13]. Stones should be repositioned to more favorable calyces prior to laser treatment. Backloading the ureteroscope over the stiff portion of a wire also risks internal channel punctures and flap creation.

The most fragile portion of the scope is the active deflection unit. Excessive force/stress on the deflection mechanism expedites deterioration, typically occurring when the deflection circumference is greater than the renal pelvis size [9, 13]. Newer scopes with exaggerated active deflection may therefore shorten the interval between major repairs [14]. Duration of scope use inside the patient and patient’s body mass index were correlated with loss of downward deflection during use [15]. Lastly, applying excessive torque on the semirigid scope shaft leads to image distortion and scope failure [16].

To improve longevity, handling is critical: this includes maintaining the scope loosely coiled in transit, holding the handpiece with tip relaxed in a dependent position, straightening the scope into neutral position before advancing instruments through the channel, and using jelly or silicone lubricants to reduce frictional forces within the working channels. Ensuring both proximal and distal sections of the scope are synchronized mitigates torque-twisting damage. Other recommendations include using UAS, nitinol devices, smaller holmium laser fibers, and laser tip visualization during use [17].

### Stone migration

#### Ascending/proximal migration

Proximal stone migration occurs in 3.5–12.2% of URS cases [1, 3, 4, 18, 19]. This increases operative/anesthesia time and may prevent case completion, subjecting a patient to additional anesthetic. Risks of proximal stone migration include initial proximal stone location, degree of ureteral dilation, pneumatic or electrohydraulic lithotrites, laser settings, and increased fluid irrigation. Antiretropulsion products are available to prevent proximal stone migration [1].

#### Ureteral stone extrusion

Stone migration into the ureteral wall occurs <1% in URS [20, 21]. Stone removal is technically difficult after extrusion, and further action should be done with caution and care.

#### Intramural stone extrusion

Intramural stone migration (“submucosal stone”) is stone extrusion through the ureteral mucosa, injuring the inner ureteral lining. This usually occurs during stone

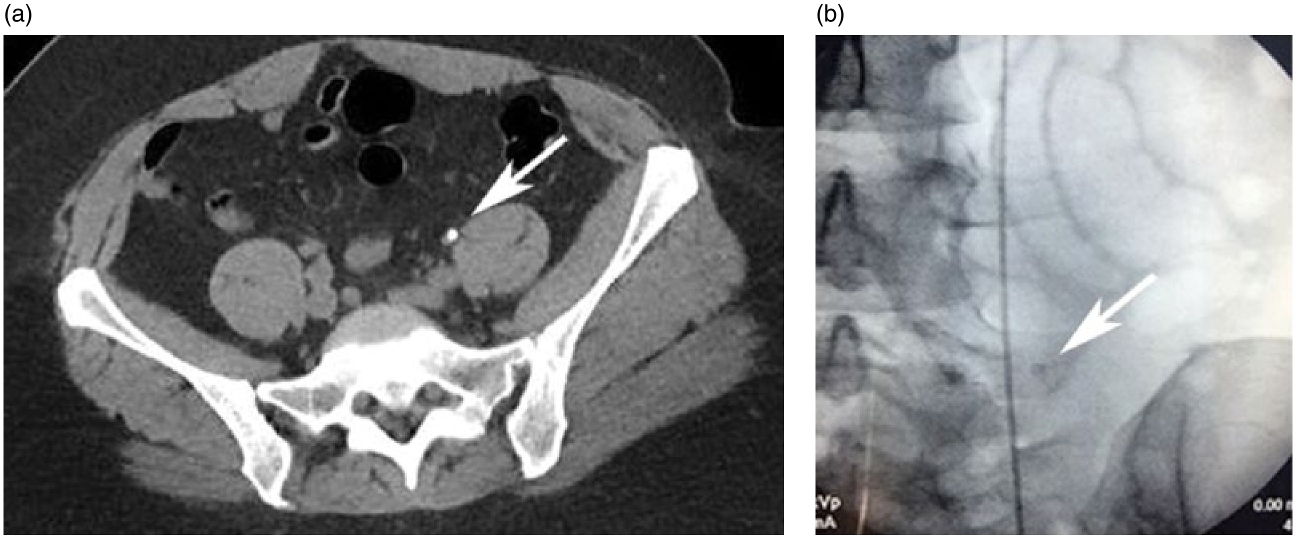

**Figure 56.2** Misdiagnosed ureteral stone. CT scan shows stone appearing to be in the mid left ureter; however; URS shows stone external to the ureter.

treatment and often with an impacted stone. Submucosal stones have been identified as predisposing to stricture formation and may become a nidus for stone growth [20, 21]. Stone fragments embedded within urothelium stimulate inflammation that may result in stone granuloma [22]. This raises concern during stone dusting techniques performed after ureteral perforation. Fragments may imbed within perforations as they pass down the ureter. Submucosal stones are typically diagnosed endoscopically as bulges from the inner ureteral wall, but can also be diagnosed with computed tomography (CT).

Therapeutic approach is controversial because with observation a granuloma or stricture may occur, but extraction remains difficult and may result in further ureteral injury with worse long-term sequelae. If a submucosal stone is identified during atraumatic URS (presumed chronic) laser excision followed by ureteral stent placement is recommended. Failure to remove stones requires long-term follow-up to ensure that a stricture does not occur.

### Extramural stone migration: complete extrusion

Extramural stone migration ("lost stone") extruding past full thickness of the ureter is rare. This was more common prior to holmium, when higher power lithotrites were used. Risk factors for complete extrusion include improper endoscopic techniques, ureteral edema, poor blood supply of the ureteral segment, microtrauma to the ureteral segment, high intraluminal pressure from fluid irrigation, and outward compressive force on the stone into the ureteral wall from scope or instrument. The most serious sequelae are stricture and fluid extravasation, and retroperitoneal abscess can occur rarely if urinary tract infection (UTI)/bacteruria is present [23]. Stone retrieval should not be attempted [23, 24], but a ureteral stent should be placed due to perforation. Stone location should be documented, as future imaging studies may falsely diagnose ureteral calculus (Figure 56.2). Follow-up upper tract imaging is indicated to exclude stricture formation and document extramural calculus position.

## Ureteral injury

### Classification

Ureteral injury is the most frequent complication; however, it is typically managed with a ureteral stent. Delayed sequelae of significant ureteral injury and urine extravasation include prolonged ileus, urinary obstruction, urinoma, azotemia, fever, persistent flank pain, fistula formation, and sepsis [25]. Several validated classification systems have been developed for ureteral injuries (Table 56.2) [26–28].

### Management

Failed conservative management or high-grade injuries require reconstruction. Timing of repair is either within first 5 days or deferred at least 6 weeks until resolution of acute periureteral inflammation. With a nephrostomy tube in place, retrograde and antegrade radiographic studies may be performed (Figure 56.3). Cystogram should also be performed prior to any potential bladder involvement in reconstruction. The optimal repair is based on injury location, degree of ureteral loss, and surgeon comfort/training (Table 56.3).

**Table 56.2** Classification of ureteral injuries.

| | Grade | Description | Management |
|---|---|---|---|
| AAST[a] | 1 | Contusion or hematoma without devascularization | Ureteral stent |
| | 2 | <50% transection | Ureteral stent (or nephrostomy), may require surgical reconstruction |
| | 3 | >50% transection | Ureteral stent (or nephrostomy), may require surgical reconstruction |
| | 4 | Complete transection with <2 cm devascularization | Surgical reconstruction |
| | 5 | Avulsion with >2 cm devascularization | Surgical reconstruction |
| | | Note: advance one grade for bilateral up to grade 3. | |
| Traxer and Thomas | 0 | No lesion found or only mucosal petechiae | No Intervention required, consider ureteral stent 1–2 weeks |
| | 1 | Ureteral mucosal erosion without smooth muscle injury | Ureteral stent 1–2 weeks |
| | 2 | Ureteral wall injury involving mucosa and smooth muscle (periureteral fat not seen) | Ureteral stent 3–6 weeks |
| | 3 | Ureteral wall injury involving adventitial perforation (periureteral fat seen) | Ureteral stent and/or nephrostomy, may require surgical reconstruction |
| | 4 | Total ureteral avulsion | Surgical reconstruction |
| PULS[b] | 0 | No lesion or insignificant mucosal abrasions: contusions with minimal hematoma, mucosal moulding via guidewire | No intervention required |
| | 1 | Superficial mucosal lesion and/or significant mucosal edema/hematoma: superficial bleeding/tears of the mucosa and/or mucosal edema or hematoma | No intervention required, consider ureteral stent (<1 week) |
| | 2 | Submucosal lesion: deep tear of the mucosal and submucosal layer (ureteral integrity, no extravasation) | Short-duration ureteral stent (1–2 weeks) |
| | 3 | Perforation <50% (partial transection) | Moderate-duration ureteral stent (3–4 weeks) |
| | 4 | Perforation 50–99% (partial transection) | Long-duration ureteral stent (6–12 weeks) (remaining tissue bridge enables conservative therapeutic attempt); likely to require surgical reconstruction |
| | 5 | Complete transection | Ureteral stent or nephrostomy to temporize; surgical reconstruction is mandatory |

## Mucosal abrasion

Mucosal abrasion can occur to varying degrees in all URS procedures, especially with UAS use (Figure 56.4). Postoperatively, these abrasions may result in ureteral obstruction from edema or clotted blood [29]. Incidence of mucosal abrasion has decreased with newer, smaller endoscopes [27]. Multiple passes through the ureter increases the likelihood of mucosal abrasion [16].

## False passage/mucosal flap

Mucosal perforation without full-thickness involvement occurs in 1.1–2.8% of cases [1]. This can occur when attempting to pass a wire past an impacted stone or during semirigid scope advancement into the ureteral wall. Passing wire without smooth advancement up the ureter or the appearance of abnormal anatomy on fluoroscopy should alert the surgeon to the possibility of false passage. Alternatively, the wire may follow the path of the ureter and collecting system within a flap (Figure 56.5) and radiographically appear to be in position. This presents a subtle but very dangerous situation, which if not recognized can lead to major ureteral injury. Immediately, the wire should be withdrawn and repositioned. Contrast enhancement of the ureter or direct-vision endoscopy can aid in correcting the misguided wire. Peri-adventitial extravasation confirms the false passage or mucosal flap. If minimal injury exists, case termination is not always necessary, but a stent should be placed at the conclusion. If injury seems more extensive immediate stenting is always a prudent decision.

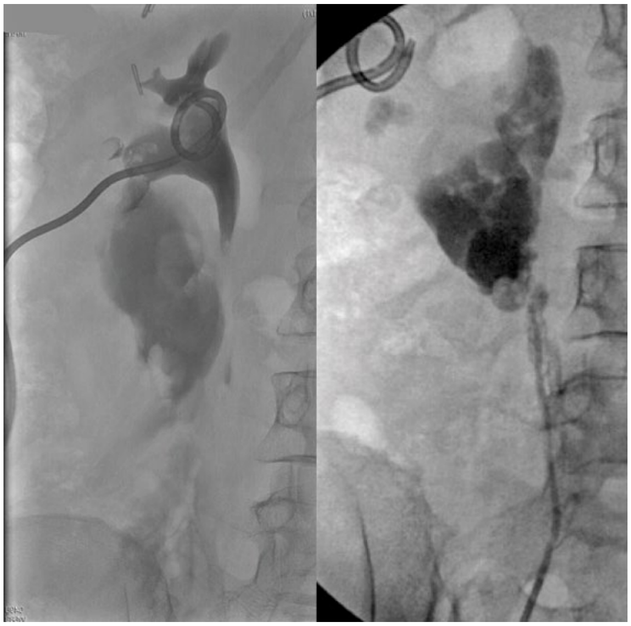

**Figure 56.3** Antegrade and retrograde fluoroscopic studies help to identify and quantify ureteral injury in preparation for repair.

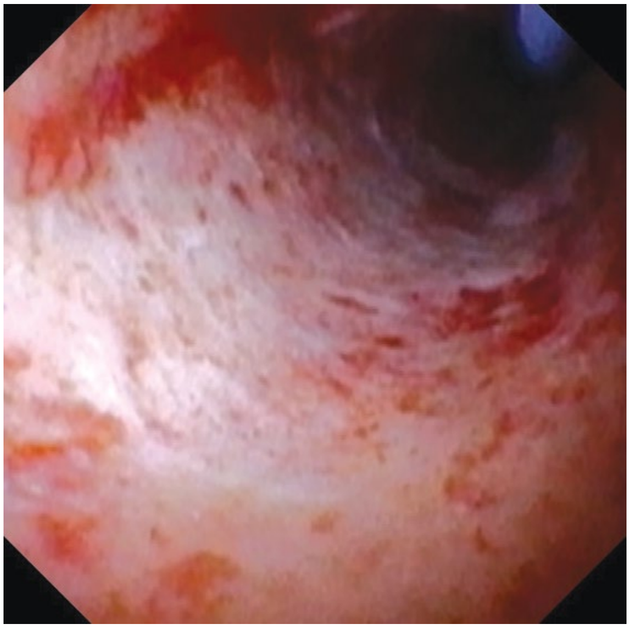

**Figure 56.4** Mucosal abrasion of ureter after removal of access sheath.

**Table 56.3** Principles of ureteral reconstruction.

| Ureteral injury | Reconstructive options |
|---|---|
| **Proximal ureter** | |
| Small defect (<2 cm) | Ureteropyelostomy (dismembered pyeloplasty)<br>Ureteroureterostomy<br>Ureterocalycostomy |
| Large defect (>2 cm) | Renal pelvis flap (Scardino-Prince vertical flap, Culp-DeWeerd spiral flap)<br>Ureterocalycostomy (with renal mobilization)<br>Ureteroplasty with gastrointestinal segment (buccal, appendix)<br>Ureteral interposition with gastrointestinal segment (buccal, appendix, ileum)<br>Ureteroneocystotomy with Boari flap (Long) |

- Debridement of necrotic/fibrotic tissue
- Wide spatulation of ureteral ends
- Watertight mucosa-to-mucosa anastomosis (interrupted or running)
- Absorbable suture
- Bridge anastomosis with internal stent
- Consideration for external drain
- Isolation of reconstructed ureter with peritoneum or omentum

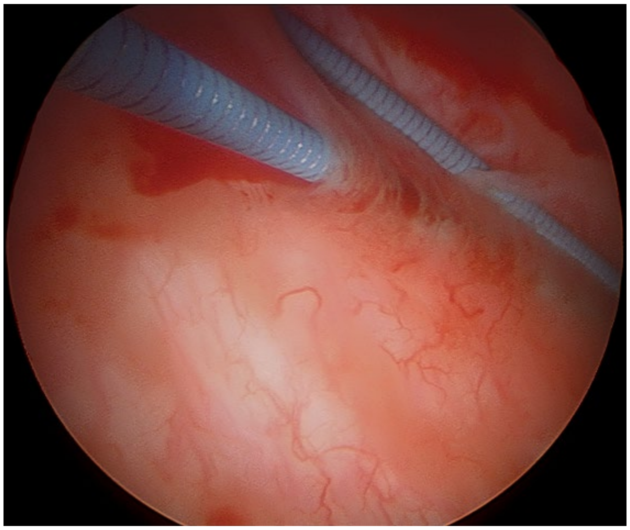

**Figure 56.5** Mucosal flap created with advancing second wire. Radiographically, this wire follows the path of the ureter and can be mistaken as being intraluminal.

## Perforation

Large-cohort studies of stone-related URS cases have reported ureteral perforation at 0–18% [2, 30]. Perforations occur from passing wires, ureteral dilation, ureteroscope passage, instrument manipulation, lithotripsy, and unexpected patient movement [7]. Increased operative time and procedure difficulty are independent risk factors [2]. Additional risks include ureteral tortuosity, periureteral fibrosis, stone impaction, ureteral stenosis/stricture, and patient movement.

These injuries are typically recognized endoscopically, with visible disruption of the ureteral wall or visible fat (Figure 56.6). The diagnosis can also be made radiographically with contrast extravasation. Small perforations do not necessarily merit immediate cessation of a case but do require stenting. Large perforations do require immediate termination and stenting. Percutaneous nephrostomy tube placement is indicated if a stent cannot be successfully placed. Large urinoma requires percutaneous drainage. A ureteral stent is typically maintained for 2–4 weeks to facilitate healing of the perforated segment. A bladder catheter should be considered for maximum drainage if perforation is significant with large extravasation. Follow-up imaging is obtained to assess healing and drainage [31, 32]. These patients carry long-term risk of stricture [33].

## Ureteral access sheath

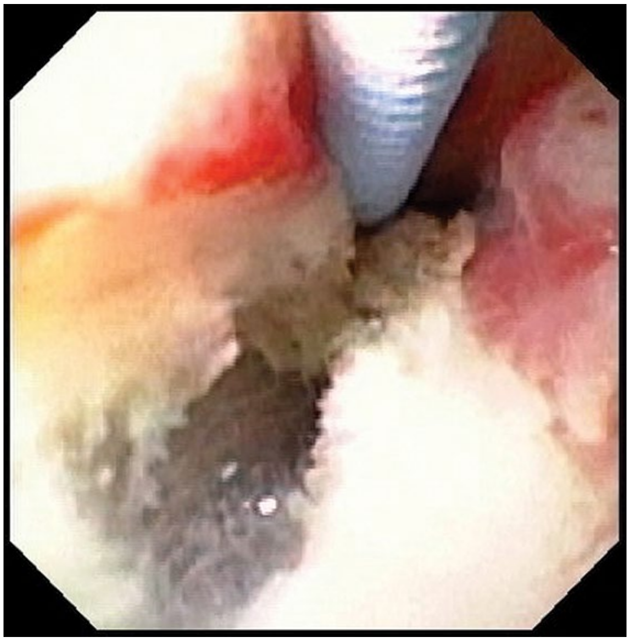

**Figure 56.6** Ureteral perforation recognized endoscopically.

Evidence supports that access sheaths provide the benefit of decreased operative time, simplified re-entry into the ureter, decreased operative costs, and improved stone-free rate [34, 35]. UAS further provides lower intrarenal pressure by facilitating continuous flow irrigation and subsequently reduces the risk of systemic infection [36].

Ureteral injury can occur with UAS placement, but these are typically low-grade and self-limiting. Traxer and Thomas reported 47% ureteral wall lesions following UAS placement, of which 85% were low grade [27] but long-term sequelae were not reported. A retrospective review of 71 patients undergoing endoscopy with UAS found only one patient developing a stricture; however, this patient had recurrent stones and stricture developed proximal to placement of the 12/14 Fr UAS [37].

To avoid significant unnecessary complications, retrograde ureterogram should be performed prior to UAS placement to rule out ureteral stone or stenosis. If the UAS does not pass easily under fluoroscopy, the inner tapered dilator portion should be used independent of the sheath to predilate the ureter before passing the combined dilator and sheath. If still unsuccessful, sequential tapered dilation or radial balloon dilation may be performed in ureteral dilation. We do not recommend dilation of proximal ureter due to higher risk of major ureter injury. Prestenting in cases of difficult UAS placement is reasonable but routine prestenting for all cases is not supported. UAS larger than 12/14 Fr should not be used without prior stenting or dilation to avoid inadvertent ureteral damage.

## Ureteral avulsion

Ureteral avulsion is widely considered the most devastating complication of URS and is fortunately rare 0.1–0.5% [3, 19].

It is an extensive degloving injury to the ureter, resulting in full- (mucosal and muscularis) or partial-thickness (mucosal) discontinuity of the ureter. This typically results from overstretching the ureter, most commonly after difficult manipulation of an impacted ureteral stone or forceful basketing [31, 32]. The proximal one-third of the ureter is most prone because it is less muscular. Some patients may be predisposed to injury due to loss of ureteral elastic fibers and chronic ureteritis or fibrosis, which may result from prior endourologic procedures or previous trauma [38]. Avulsion may occur during attempted removal of a stone fragment too large for the ureter to accommodate and can also occur as the ureter is initially instrumented, such as advancing a ureteral dilator, access sheath, or ureteroscope in a retrograde fashion. Avulsion can occur during withdrawal of basket with unrecognized tissue entrapment. This is often recognized only after a portion of ureter is withdrawn into the bladder or out of the patient (Figure 56.7) along with the basket often attached to the stone. If retrograde pyelography is performed, complete avulsion will demonstrate extravasation of contrast, without opacification of ureter and collecting system proximal to the disruption.

The distal ureter may be avulsed upward with scope advancement if the distal segment has extensive edema, inflammation, stenosis, or tortuosity usually caused by impacted stones [39–41]. This may also occur without initial recognition because avulsion occurs behind the tip of the scope. Recognition of injury occurs with scope removal and long intussuscepted ureter tissue, known as "scabbard" injury, as seen with a sword in a scabbard. The earliest point of recognition is the haptic sensation of a tight ureter that requires additional force to advance or withdraw the scope. The semirigid ureteroscope has a tapered shaft, and although the tip may appear to be passing adequately through the ureter, the proximal shaft may be too large to pass a narrow segment. Scabbard injury results in the loss of a large ureteral segment that typically requires autotransplantation or bowel interposition. Thus, clipping the proximal ureter and placing a nephrostomy drain would be helpful in the acute setting to prepare for definitive treatment.

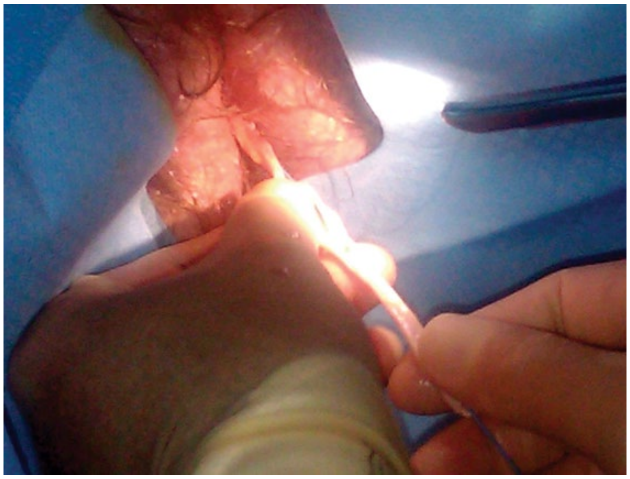

**Figure 56.7** Ureteral avulsion recognized after removing the ureteroscope from the patient. Surgeon is advancing wire up the prolapsed ureter attempting to temporize injury with stent placement.

To reduce risk of avulsion, stones should be removed and instruments manipulated under direct vision, ensuring stone fragments are smaller than the lumen before removal. *Increased resistance may be the only sign that impending injury is about to occur*. UAS can be protective but the urologist should be mindful that as a stone is drawn into the access sheath, urothelium may become entrapped resulting in injury at this site. Proponents of the stone dusting technique cite the decreased risk of ureter injury as it avoids basket use altogether.

#### Incomplete (urothelial) ureteral avulsion/intussusception

Incomplete ureteral avulsion occurs similar to complete avulsion; however, only the inner urothelial layer of the ureter is disrupted and stripped, leaving behind the outer muscularis layer. This occurs in the direction of the scope's (or instrument's) movement and can occur in either direction. Urothelial stripping often arises at a narrowed ureteral segment and is often associated with extraction of a large calculi or polypoid urothelial lesion. Retrograde pyelogram demonstrates containment of contrast inside a ragged, irregular-looking lumen. Without the urothelial layer, these ureters most often scar with large segment stricture and become nonfunctional. Immediate sequelae are less severe than with complete avulsion. Initial management involves placement of a stent (or percutaneous nephrostomy tube and attempting antegrade stent) followed by close monitoring for 6 weeks. Only rarely is ureteral healing over a stent successful. Usually, staged ureteral reconstruction is necessary.

### Lithotrite injury

Lithotrite use can mechanically or thermally injure the ureter, causing bleeding, perforation, or tissue ischemia. Bleeding is typically minor and self-limiting, but even minimal bleeding can reduce visibility. Moderate-to-severe bleeding may require procedure termination. Reduced visibility from hemorrhage has been reported as the most frequently encountered reason for a repeat or staged endoscopic procedure [42]. Patients remaining on anticoagulation therapy during surgery intrinsically have greater bleeding risk; however, these patients are at no increased risk of adverse events related to URS with laser lithotripsy [43]. Lithotripsy near the crossing of the iliac artery should be performed with extreme care. Endoscopic bleeding involving an iliac vessel is exceedingly rare but is a potential source of catastrophic hemorrhage.

Thermal injury from lithotripsy may result in various lesions from small mucosal defects to large necrotic areas. Rate of complication is significantly higher with pneumatic over laser lithotripsy [44, 45]. The neodymium-doped (Nd):YAG holmium laser penetrates 5–6 mm when in contact with the urothelium. This contact laser produces energy that is absorbed by water; thus, thermal lesions are produced 0.5–1 mm deep [46]. Higher energy settings in newer-generation laser units (>1 J) can produce greater thermal injury. Injury is avoided by limiting urothelial contact, which is achieved by constant visualization of the laser tip, maintaining a short working distance, and keeping the laser fiber parallel to the ureteral wall. If urothelial contact is intentional (for bleeding control or upper tract urothelial tumor ablation), the urologist should be judicious about the amount of thermal injury induced, ensuring it doesn't exceed that needed for therapy. These patients also require close follow-up with imaging to rule out stricture development.

### Stone basket entrapment

Entrapment of a basket device on a stone occurs in approximately 0.5% of cases where a basket is used [21]. This is attributed to grasping a stone or fragment too large for removal through the ureter, resulting in a stone entrapped by the basket or snaring of the urothelium. Forced retraction of an entrapped basket is often the preceding event to severe ureteral injury. If a basket has engaged a stone that becomes stuck or does not easily pass down the ureter, the first maneuver is to gently advance the stone more proximal and disengage the stone using the basket mechanism. The next maneuver should be to cut the basket wiring with scissors just beyond the handle or basket disassembly if basket preservation is necessary (Video 56.1). Once cut or disassembled, the ureteroscope can be withdrawn from the ureter removing the basket from the working channel. This permits re-introduction of the ureteroscope with a vacant working channel and the ability to perform laser lithotripsy. One or two of the nitinol wires can be fractured with laser to disengage an entrapped stone. It is important to spare some of the basket wires or discontinuity of the basket and foreign body deposit into the upper urinary tract will occur. Nitinol baskets are easily withdrawn after being lasered because of their soft nature. Steel baskets have the potential to cause ureteral injury during removal and may potentially require delayed, staged removal, or even an open procedure for safe removal.

### Pressure-related injury

High intrapelvic pressure, from a retrograde pyelogram or URS, can lead to pressure-related kidney injury. This fluid pressure can produce urinary extravasation, urinoma, and sepsis (if bacteriuria present) [16]. High intrapelvic pressure, from an iatrogenic or obstructing source, may lead to pyelosinus extravasation from the calyceal fornices. Extravasation frequently exits the renal hilus and resides in the retroperitoneum, which is visualized with contrast around the ureter, simulating a ureteral rupture, and may accumulate outside the contour of the kidney. Extravasation decreases immediately after addressing the source. Recurrent extravasation of this nature may lead to parapelvic pseudocyst or – less commonly – periureteral pseudocyst, the formation of a urinoma at the site of the extravasation. To avoid iatrogenic forniceal rupture, decreased irrigation fluid pressure and/or UAS are recommended.

## Early postoperative complications

### Residual stone

Although complete stone-free status is the optimal outcome, residual stones are fairly common after these procedures. Providing appropriate preoperative patient expectation is important. Patients should always understand the possibility of requiring multiple procedures. Adjunctive alpha-blocker therapy may facilitate passage of residual fragments. Post-URS obstruction from stone fragments can be prevented with ureteral stenting. If obstruction occurs, a stent or nephrostomy tube should be placed in patients with severe symptoms or compromised renal function. Repeat URS or shock-wave lithotripsy provides a definitive treatment.

### Urinary extravasation/urinoma

Urine extravasation, occurring in 0.6–1% cases, may occur subsequent to ureteral wall or collecting system disruption with potential for retroperitoneal urinoma formation [18]. This reporting may be underestimated since retrograde pyelography is always performed at the conclusion of ureteroscopic procedures, and a small amount of urine extravasation into the retroperitoneum usually has no clinical significance. Risk is associated with an impacted stone, ureteral perforation, and laser injury [16]. Intraoperative extravasation of irrigation can potentially enter the retroperitoneum and undergo

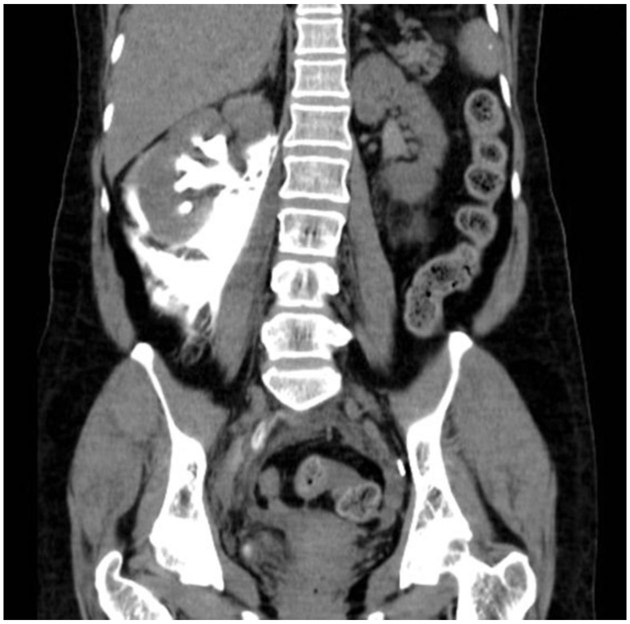

**Figure 56.8** Large extravasation of urine seen on noncontrasted CT performed after a previously contrast-enhanced study.

reabsorption resulting in fluid overload, hyponatremia, and hemolysis; therefore, saline solution is recommended. A urinoma may become infected, requiring drainage and antibiotics, which presents with pain, fever, or ileus. If urine extravasation is suspected, diagnostic studies (e.g. retrograde pyelography, intravenous pyelography, or CT urography) are required to determine further management.

Management involves urinary drainage with stent and/or nephrostomy tube. Significant extravasation (Figure 56.8) may require ureteral stenting and nephrostomy tube drainage for maximal urinary diversion. A foley catheter may be considered as adjunct. Often times with maximum drainage of the ureter and collecting system, appropriate healing will occur without sequelae. If the urinoma is symptomatic, suspected to be infected, or persists despite adequate renal drainage, a percutaneous drain should be placed by interventional radiology, and fluid culture should be obtained. Antibiotics should be administered to reduce the risk of infected urine and abscess formation. A ureteral stent should remain in place 2–6 weeks with scheduled follow-up imaging to ensure proper healing and adequate draining [31, 32].

## Urinary obstruction

With instrumentation of the upper tract, the delicate ureter undergoing intraluminal maneuvers is inevitably subject to iatrogenic trauma, which can result in local edema, ureteral spasms, and bleeding with clot formation. This may result in ureteral obstruction causing post-URS renal colic and hydronephrosis, with the incidence ranging 4–9% [47, 48]. Obstruction is typically self-limiting and managed conservatively. Often, patients can be managed with alpha-blockade and steroid or nonsteroid anti-inflammatory agents, with symptom resolution within several days. Persistent or refractory pain warrants imaging to identify other potential diagnoses or to confirm obstruction, determine its degree, and establish its precise location. Definitive treatment is ureteral stent placement. The need for replacing a ureteral stent after removal has been reported as high as 2.6% [6].

## Neuromusculoskeletal complications

Proper positioning and appropriate padding of pressure points is imperative to mitigate neuromuscular damage. Appropriate dorsal lithotomy positioning involves the anterior-superior iliac spine aligned with the lower break, with hips flexed 80–100° and abducted 30–45°. If boots are used, heels should be well supported, and the pressure on the calves and lateral knee should be minimized. Special attention is necessary for obese or contracted/stiff patients. The most common injury is to the common peroneal nerve, which would clinically manifest as foot drop. Risk factors include maintaining this position >4 hours, body mass index >20 kg/m$^2$, and smoking. Other less common nerve injuries related to position include obturator, posterior tibial, and pudendal nerves, which warrant neurology and/or physical therapy consultations.

## Hemorrhage

Hemorrhage from URS is typically minor and self-limiting and rarely warrants monitoring or intervention. Mild bleeding has been reported as the most common intraoperative complication at a rate of 1.4%, and the most common reason for requiring repeat URS [3, 49]. Innate bleeding risks should be screened using patient history and labs seeking to identify underlying coagulopathy or anticoagulant use. These patients should be counseled prior to procedure, and measures should be implemented to reduce risk, such as holding medications prior to surgery. URS is the preferred surgical option in those with bleeding diathesis. These authors prestent patients whose risks of thromboembolic event precludes cessation of anticoagulants.

Intraoperative bleeding is managed by aborting the procedure, stent placement, and fluid hydration. Profuse or pulsatile intraoperative bleeding could indicate iliac vessel injury. Significant postoperative bleed, especially with drop in hematocrit, warrants immediate workup with contrasted imaging studies or interventional arteriogram. Ureteral balloon placed in the distal ureter can temporize bleeding until interventional or vascular repair is achieved. Perinephric (subcapsular) hematoma is suspected with flank pain out of proportion and subsequently diagnosed with imaging. This is a rare complication attributed to laser misfiring, wire perforation, high-pressure irrigation, and forceful retrograde pyelogram and is managed with observation, reassurance, and analgesia. Occasionally, a ureteral stent is warranted and, rarely, a transfusion.

### Venous thromboembolism

Deep vein thrombosis is a rarely encountered surgical complication. It carries the potentially fatal sequel of pulmonary thromboembolism, which is exceedingly rare (0.02%) [3]. Pulmonary thromboembolism is one of the most common causes of nonsurgical death in patients undergoing urologic surgery and is associated with significant long-term morbidity [50]. The American Urological Association (AUA) Best Practice Statement does not specify URS procedures; however, all patients should be provided mechanical compression modalities and encouraged for early ambulation, and high-risk patients should be considered for pharmacologic prophylaxis [50].

### Urinary tract infection

Complicated UTI and pyelonephritis have a post-URS incidence of 1–3.7% [3, 51]. General risks of infectious complications include older age, obesity, female gender, nutrition or immune system impairment, diabetes mellitus, smoking, coexisting bodily infection, and increased bacterial load [52]. Increased bacterial load is associated with history of urogenital infections, preceding or recent hospitalization, urinary obstruction, large urinary stone, or long-term urinary drainage tubes [52]. The AUA recommends antibiotic prophylaxis for all patients undergoing URS; however, the European Association of Urology (EAU) only recommends prophylaxis for select URS cases of proximal or impacted stones and patients with risk factors associated with infectious complications [52, 53].

Martov retrospectively reviewed the Clinical Research Office of the Endourological Society (CROES) database identifying that in patients having negative baseline urine culture, the rates of post-URS UTI and fever were not reduced by preoperative antibiotic prophylaxis; moreover, female patients or those with impaired immunity (such as Crohn's disease) and higher American Society of Anesthesiologists (ASA) grades were at greatest risk of post-URS fever or infection. However, antibiotic use was not controlled, and conceivably higher risk patients were provided antimicrobial prophylaxis [51]. Although several randomized controled trials have reported that antibiotic prophylaxis significantly decreased bacteriuria following URS [54, 55], Ramaswamy and Shah demonstrated that a course of prophylactic antibiotics following an uncomplicated ureteroscopic procedure provided no benefit in preventing infectious complications, and is therefore not recommended [56]. A study reviewing the CROES data showed a significantly reduced incidence of postoperative infectious complications with a UAS (fever 28 vs. 39%, UTI 18 vs. 24%, and sepsis 4 vs. 15%, for UAS vs. non-UAS groups, respectively) [57].

A urine culture or urinalysis should be obtained prior to URS, and bacteriuria or positive culture should be treated prior to surgery. If frank pus or pyonephrosis is encountered intraoperatively, especially in the setting of obstruction, the case should be terminated with placement of stent or nephrostomy tube and antibiotics tailored towards cultures.

### Infection/sepsis

Sepsis is an uncommon but life-threatening complication of URS, reported at 0.3% [3]. Retrograde seeding of bacteruria or infected calculi are contributory factors. The surgeon should be cognizant of fluid pressure transmitted to the upper tracts, especially in patients with chronic indwelling urinary drainage tubes or urinary stasis. Additional antibiotics may be used postprocedure for higher-risk patients. Renal urine aspirate and stone culture can be obtained intraoperatively to guide antibiotic administration if infection does manifest. A significantly reduced incidence of infectious complications (specifically >50% reduction in sepsis) has been reported in patients treated using a UAS [51].

## Late postoperative complications

### Ureteral stricture

The miniaturization of technology and improved technique has led to dramatic decrease in stricture rates. Contemporary studies suggest stricture incidence of 0.5–4% [32, 58, 59] with some reporting a consistently infrequent rate of <1% [3, 6, 60–62]. Strictures (Figure 56.9) develop secondarily to inflammatory processes following devascularizing or ischemic injury to the urothelium, usually from direct mechanical trauma, iatrogenic mucosal lesions, perforation, submucosal dissection, relative ischemia, dilation, thermal lesions, radiation, impacted stone, and periureteral fibrosis [63]. However, some strictures develop without an identifiable precipitator. Presentation can be either symptomatic or asymptomatic ("silent obstruction").

Stone impaction >2 months carries a greatly increased incidence of stricture [63]. Ureteral perforation increases

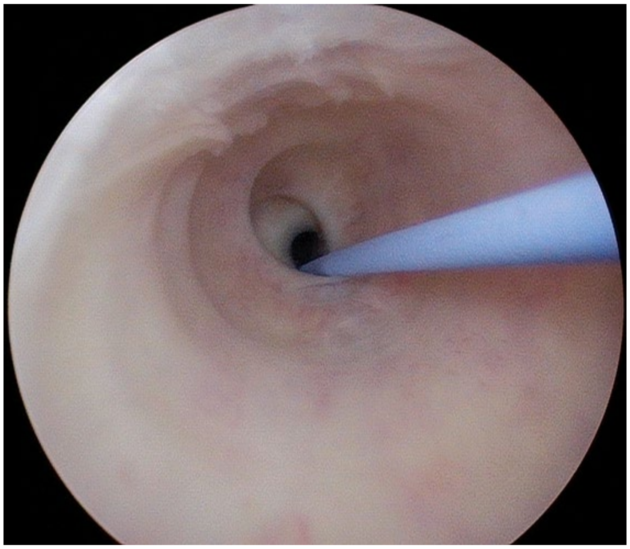

**Figure 56.9** Ureteral stricture recognized endoscopically.

stricture formation simply as an ischemic event; however, ureteral perforation at the site of stone impaction was identified as the greatest primary risk factor for stricture formation [33, 63, 64]. If perforation is identified, stenting for 2–3 weeks may decrease the risk of stenosis [33]. Some investigators suggest ureteral balloon as a precipitating event to stricture formation but a multi-institutional study showed only one stricture (0.9%) developed in 151 patients who underwent balloon dilation [7]. The use of UAS does not seem to significantly increase the risk of stricture formation [37].

In order to prevent missing the rare but potentially catastrophic silent obstruction the AUA Guideline Panel recommends routine postoperative ultrasound (±kidney, ureter, and bladder) imaging after URS. The relatively low cost and lack of ionizing radiation with ultrasonography justifies its use.

Management of ureteral stricture is discussed in other chapters in this volume. Briefly, short (<1 cm) diaphanous strictures typically can be treated endoscopically, while long (>2 cm) typically require more invasive procedures for a durable outcome. Those intermediate length strictures (1–2 cm) require a balanced assessment of patient acuity and durability of technique; e.g. younger, healthier patients likely needing more durable procedure and older, less healthy patients perhaps benefiting from less invasive procedures.

### Urethral stricture

Any transurethral procedure has the potential to injure or scar the segments of the urinary tract undergoing instrumentation. As such, URS procedures performed in a retrograde fashion are typically transurethral. The incidence of urethral stenosis in women is extremely rare, but it is more commonly observed in males. This complication should be suspected in any patient with a history of transurethral instrumentation who has new onset voiding symptoms, split stream, or change in urinary flow pattern. This diagnosis can be worked up with uroflowmetry and followed with cystoscopy and surgical management, as needed.

### Persistent vesicoureteral reflux

Vesicoureteral reflux may be present after URS even if ureteral dilation was not performed. Its incidence has been reported as high as 10% within the first 24 hours post-URS. Resolution of vesicoureteral reflux is typically observed within 2 weeks; however, 5–10% of these patients (mostly those having undergone ureteral dilation, incision of the ureteral orifice, or excised lesions at the intramural ureter) demonstrate persistent vesicoureteral reflux 3–20 months after their procedure [33]. Theoretically, persistent vesicoureteral reflux can increase the risk of upper tract infections in the presence of lower tract bacteriuria, but indication for surgical correction is rare. Grades 1–3 sterile reflux typically have no consequences in adult populations, and therefore radiographic vesicoureteral reflux evaluation after URS is not routine [65]. If treatment is required because of recurrent upper tract infections or high-pressure voiding, bulking agents are injected at 6 o'clock beneath the ureteral orifice and are usually sufficient to reduce the reflux. Formal antirefluxing reimplantation can be performed but is exceedingly rare.

## Conclusion

- Adherence to general safety rules for endourology will help minimize perioperative complications: a safety wire is essential to maintaining access. Always visualize ureteroscope advancement, working instruments, and energy sources. When unsure or encountering difficulty during a procedure, the urologist should continue with extreme caution, using fluoroscopy for orientation.
- Patient selection, appropriate procedure selection, and surgical planning are critical to successful outcomes.
- Complications can typically be conservatively managed, with opportunities for staged and successful outcomes using either a repeat or alternative approach.
- Forced maneuvers must be avoided with low threshold for stenting and staging a procedure, if difficulty is encountered.

# Retrograde Intrarenal Surgery in the Future: Robotics

*Anup Patel*

*Consultant Urological Surgeon, London, UK*

## Introduction

As the world enters the fourth industrial revolution, there will be rapid evolution in the areas of artificial intelligence (AI), robotics, three-dimensional (3D) printing, nanotechnology, genetics, and biotechnology. "Robots" have been part of human society since before Leonardo Da Vinci described gears, wheels, and pulleys to animate a robotic knight for a Milan pageant in the 1490s. *Robot*, a derivation of the Czech word "robota" from a 1920 play entitled *R.U.R.* (*Rossumovi Univerzalini Roboti*) by Czech author Karel Capek, meant forced labor or serf. Capek described fictional human-like machines that continuously performed repetitive hard, dull, or dangerous complicated tasks for their human counterparts without feeling. The machines eventually became "resentful," rebelled, and killed all the humans. Consequently, over time, the word "robot" has encompassed several meanings including that of a brutal human being who has become insensitive or machine-like because of overwork and mistreatment. In 1939, after meeting Ernest and Otto Binder at the Queens Science Fiction Society, who had published a story entitled *I, Robot* about a sympathetic misunderstood robot called Adam Link (who was motivated by love and honor), and following a conversation a year later with John W. Campbell, Isaac Asimov introduced his Three Laws of Robotics in a short story called "Runaround."

1) A robot may not injure a human being or, through inaction, allow a human being to come to harm.
2) A robot must obey the orders given it by human beings except where such orders would conflict with the First Law.
3) A robot must protect its own existence as long as such protection does not conflict with the First or Second Laws.

A fourth law was later added:

4) A robot may not harm humanity, or, by inaction, allow humanity to come to harm.

Since then, robots have been remade in mankind's image, and popularized by the televisual industry. Before Azimov, Edgar Allen Poe (1839) related the story of a wounded soldier whose body was rebuilt with synthetic parts. During the early part of the space race (1960) this was termed a cybernetic organism, for it was envisaged that blending technology with astronauts' bodies could help endurance and survival in space. This led to a plethora of medical technologies such as pacemakers, insulin pumps, cochlear implants, prosthetics, and exo-suits, all of which are already integrated into human society.

In today's world, the real issues regarding robots' future roles center over debate as to whether they will primarily augment or replace current human functions. Autonomous robotic technology has increasingly replaced traditional tedious repetitive industrial human manufacturing roles, performing dull, dirty, and dangerous tasks, leaving their human counterparts in the shade for both accuracy and efficiency. Simultaneously, programmable and master/slave-controlled drone technology, automated driverless vehicles (cars and airplanes), and crop spraying and seed dispersal farming drones have all begun to impact different aspects of daily human life, while also replacing humans in situations of inherent task-associated danger. Where sustained precision, reliability, reduced costs, and greater productivity are desired, advanced sensor robotic technology can

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

easily augment or supplant human performance without fatigue. More human functions are or will be threatened in the coming years, and some have even predicted that the ultimate supremacy of robotic over human development will be reached in only two more decades. It is a potential revolution akin to the Internet, where robots can fulfill diverse roles in society as human substitutes, companions, and partners (co-bots).

For medical applications, a key issue is whether robotic machines are better, or simply enhance human performance by lacking or reducing fatigability, allowing greater precision and efficiency over longer durations. This is particularly true for master/slave devices where expensive development costs can be offset by time saved, greater task performance precision, and increased productivity, and perhaps also consistency, particularly in repetitive or endurance-based tasks. Ideally, a master/slave human–robot partnership should enhance the capability of each individual component part provided the master can maintain concentration throughout the task. In interventional urology, robotics has already made great inroads through the use of devices that are master-independent, such as the PUMA560 [1] (1988; arm with six degrees of freedom used for brain biopsy and later for transurethral resection of prostate) and, more recently, the Cyberknife for precision radiotherapy. Zeus and Aesop (US Food and Drug Administration [FDA] approved in 1990; Computer Motion, Santa Barbara, CA, USA), were bought and quashed by Intuitive Surgical (Sunnyvale, CA, USA) in favor of their Da Vinci™, a next-generation master/slave console-controlled robotic device with endo-wrist technology (FDA approved in 2000) [2, 3]. It and the Sensei-Hansen device (Hansen Medical, Mountain View, CA, USA) [4, 5] were their urological successors, incorporating console-based 3D optical visualization with magnification, motion control and scaling, tremor reduction, and a greater range of movement and ergonomics compared to traditional instruments. Although it is beyond the scope of this chapter to examine cost-benefits, this aspect of all new technologies will be amplified in an era of economic austerity coupled to higher healthcare demands from chronic illness, fueled by obesity and ageing pandemics, and falling birth rates in the world's developed nations.

Rupel and Brown's endourological legacy of cystoscopic nephroscopy for renal stones at open surgery in 1941 [6] has been the evolution of a wide range of extracorporeal, ureteroscopic, percutaneous, and laparoscopic procedures, all embraced by urologists worldwide. The dominant large/branched renal stone treatment remains percutaneous nephrolithotomy (PCNL). Nevertheless, after two decades of evolution, classical retrograde intrarenal surgery (cRIRS) is now the most dominant endourological stone treatment modality overall. Expertise and allied technological growth has projected cRIRS to the mainstream of complex endourological stone and soft tissue treatment in the upper urinary tract. For the first time, cRIRS rightly challenges the dominant alternative of PCNL treatment of larger intrarenal calculi [7–12]. However, cRIRS for large stones remains a technically challenging procedure requiring specific expert endo-skill sets, real-time problem solving capabilities [13–15], and both physical and mental endurance. Even when ureteral access sheaths (UAS) are used (almost mandatory in this setting), and the stone(s) can be accessed and completely laser-fragmented, the single-sitting stone-free rate is limited by the operator's stamina during long dusting and "pop-corning" procedures, and the size and number of stone fragments that can safely be removed down the ureter in a safe, timely manner (in turn dependent on stone composition and hardness, and collecting system anatomy). Additional limiting factors are current flexible ureterorenoscope (FUR) design, a moving target (renal respiratory excursion) during fragmentation, and awkward calyceal anatomy, particularly if several such cases are scheduled per day. This has resulted in ≥50% secondary procedure rates to render patients stone-free. Furthermore, the surgeon depends on assistants for key task performance, to activate lasers (standby-ready and energy-rate settings adjustments), deploy nitinol baskets and capture fragments, maintain and enhance irrigant flow, aspirate, and to draw/inject contrast, while manipulating and targeting the ureterorenoscope tip. All operating room staff are exposed to radiation over a longer period (range of 1.7–56 μSv [16–18]). Meanwhile, less invasive evolutionary PCNL techniques (mini, ultra-mini, super-mini, and micro-PCNL [19–24]) have also evolved to challenge cRIRS, to gain parity or ascendancy in the current larger renal stone treatment paradigm, particularly in Asia, so further technological and technique evolution is mandated.

During the last two decades, significant changes in both semirigid and FUR design, specifically tip and shaft size reduction along with configuration changes, have facilitated easier natural orifice access into the upper urinary tract for the majority of users (albeit at the cost of increased fragility and repair costs). Greater direction and range of tip deflection (both single and dual active flexion/extension motion range) has made navigation through the intrarenal collecting system easier, allowing more urologists to reach and inspect >95% of the entire collecting system (the most challenging part being the lower antero/medial calyx, especially in a dilated pelvicalyceal system which limits use of both active and secondary passive deflection).

In 2012, ELMED (Ankara, Turkey) started developing a procedure-specific robot-assisted RIRS (RA-RIRS) device [25]. The IDEAL (idea, development, evaluation, assessment, long-term study) framework for surgical innovation stages was embraced from prototype to the commercially available Avicenna Roboflex (IDEAL stage 1), and early clinical experience with treatments performed by different experienced endourologists (IDEAL stages 2–4) was reported as follows.

## Device development

The basic Avicenna Roboflex design from prototype (Figure 57.1a) to successive versions (Figure 57.1b–d) consisted of a master control console (MCC) seating the surgeon and a manipulator arm (MA), which can now be coupled to any standard commercially available FUR using a custom-made model-specific adapter. During the early developmental phase, incremental improvements were made to the size and design of the MCC, the joysticks to control advancement, rotation, and tip deflection, and to develop a system to remotely advance-retract the laser fiber.

### Master control console design features

The current Avicenna Roboflex (version 5) MCC (Figure 57.2a) is connected to the MA unit, and its monitor is connected as a slave to the operating room stack monitor. It has key-control on-switch, with separate red push-button emergency stop (Figure 57.2b). The MCC reclining seat has adjustable height, head, and armrests. Six users can store individual seat positions and all preferred custom deflection-scaling settings in the system memory (Figure 57.3). The comfortably seated surgeon activates wheel locks, selects endoscope type, brightness, time, background screen color (one of six options), rotation precision and direction, deflection precision, and horizontal plane movement speed via the set-up menu. Moreover, they can also select low- (0.5×) or high-precision (1.5×) modes, timer stopwatch start or reset options, and define target kidney side (right or left) on the touch-screen panel (also displayed on the center right of the monitor screen). The MCC touch screen also allows control of laser fiber actuator, irrigation flow rate, short bursts of flush, and abdominal compression belt inflation to reduce renal respiratory movement (Figure 57.4). Below this on the monitor screen is the endoscope deflection and rotation icon, and above it are laser fiber and irrigation flow rate indication bars (Figure 57.5). The rotation display circle containing the endoscopic view is in the center. The surgeon controls two joysticks (with adjustable padded wrist support) to manipulate the FUR, which is mounted on the MA component. The right-hand vertical joystick bulb's "magic wheel" controls fine tip deflection akin to the handpiece of any standard FUR (Figure 57.6a), but with additional tenfold motion scaling. The deflection direction (upwards, downwards) can be programmed for logical deflection (down = tip down and up = tip up) or counterintuitive deflection (down = tip up and vice versa). The new horizontal left joystick (Figure 57.6b) allows clockwise and counterclockwise MA rotation, as well as advancement and retraction of the endoscope shaft with millimeter per second adjustment, using +/– buttons. The rotation speed, scale (2, 1, 0.5×) and MA rotation direction (clockwise or counterclockwise), and advancement can be regulated by console touch-screen control. Warning display box alerts inform the user about rotating the MA to the mounting position (90° clockwise), continuing from a particular position, or returning to the neutral position.

→

**Figure 57.1** (a) Avicenna Roboflex version 1 prototype for RA-RIRS: simple circular holder for FURS control and laser fiber movement, controlled from console with two small four-way joysticks (left for forward/backward and laser fiber in/out, right for rotation clockwise/counterclock wise, and deflection up/down). The joysticks were later modified with bigger, thicker handles. (b) Similar manipulator arm with longer horizontal movement (forward/backward movement) for easier basket application, and smaller control console with height adjustable seat. Control of the left joystick movements were unchanged, but right joystick had a thick, rotatable handle to control FUR rotation and there was another individually rotatable disk incorporated into the top of the joystick handle to control up/down deflection. (c) Version 3: new manipulator arm design (with high-precision robotic components) with open-type endoscope holder and new master control console (MCC). Rotation movements over 440° were designed for smooth precision following hand movement. Special endoscope holder was designed for easy docking with deflection control unit. A force-torque deflection mechanism sensing system was developed to protect the device against high-deflection torsion. Horizontal movement (forward/backward) was set to a speed of 22 mm/second (adjustable from 0.5 to 22 mm/second). The MCC was designed with two joysticks to control rotation and forward/backward movement (left joystick), and deflection movement on the right joystick. Laser fiber movement and vertical movement (according to patient tabletop position) were controlled from the touch screen. Later, a central precision control cylinder was added to the center of the MCC for fine tip deflection control as a modification of that version. (d) Version 4 incorporating a new interchangeable endoscope holder system to accommodate all FUR brands/models. The right joystick controlled rotation and two-stage speed control for forward/backward movements and incorporated a thumb wheel ("magic wheel") for tip deflection. Precision or scale of all rotation and tip deflection movements were selectable from the MCC touch screen. A new MCC foot-pedal unit was incorporated to control any laser or fluoroscopy foot pedals. Additional visual guidance was provided on the video monitor screen to indicate the spatial position of the FUR (such as horizontal distance, rotation angle, and deflection angle).

Connected FURS Type is: EU

**Figure 57.4** The MCC touch screen with various functions in the set-up menu: adaptation to FUR mode (i.e. American or non-American), change of rotation, deflection precision, horizontal advancement/retraction speed, laser fiber advancement and retraction, irrigation flow rate adjustment, compression belt inflation-deflation, and degree of rotation, deflection, and horizontal insertion display, along with timer and stop watch.

The assistant introduces the laser fiber at the start with the endoscope tip in a “0” straight position, with the tip cladding just visible endoscopically, and the touch-screen “eye button” in the laser fiber box is pressed. The zero button is then activated to level the fiber tip with the work-channel exit point. The endoscope can now be safely maneuvered to the stone before advancing the fiber tip 1.8 mm for safe firing. The MCC floor-mounted red right foot pedal controls laser firing, while the white left pedal controls the fluoroscopy (Figure 57.7a), both aided by compressed air cabling to a foot-pedal coupler unit (Figure 57.7b). The laser fiber foot pedal is automatically disabled when the fiber tip is within 1.6 mm of the endoscope tip (the red warning bar is a useful safety feature).

## Manipulator arm design

The MA consists of computer-controlled motor systems, a robotic arm, which holds and moves the endoscope, and the lower stabilizing arm to which vertical supports are attached in two places. The arm height can be adjusted according to the patient’s anatomy. The endoscope hand piece with appropriately placed deflection lever is fixed into the arm’s customized coupler housing and secured by double clip holders after draping (Figure 57.8). The distal vertical stabilizer is fixed to the preplaced UAS hub, while the proximal one stabilizes the straight endoscope shaft approximately 5 cm further back (Figure 57.9a). A UAS is virtually mandatory for Avicenna Roboflex procedures, due to lack of haptic

feedback, reducing risk of inadvertent ureteral injury. The custom-made coupler accepts any FUR, although initial development was made using a digital instrument (Flex-XC; Karl Storz, Tuttlingen, Germany). The MA can be rotated bidirectionally by 210° allowing overlap for a total 440° compared to 120° for humans. Miniaturized hand-piece adaptor motors allow endoscope steering lever movement for deflection and enable motion scaling of the cable-based endoscope tip movement mechanism. Due to FUR design and cabling inertia, a short lag period between robot control and endoscope tip reaction exists. This is vital for the user to understand and remember, for there is a tendency to continue MCC deflection if no immediate visible screen reaction is seen, leading to delayed deflection overshoot. The same lag occurs for the same reason when switching deflection direction. Normally, a 10° manual lever deflection moves the tip 60°. With Avicenna Roboflex, FUR tip control precision is eightfold greater than manual operation. The thumbwheel scaling precision, which can be low or high, or on a scale of 1–10 as set on the MCC, allows 10° of thumb movement to result in 3–30° of tip deflection. The applied forces were limited to 1 N/mm$^2$ for safety to minimize the risk of collecting system and endoscope injury.

Moreover, the coupling hand-piece adapter accepts placement of a micromotor-driven actuator system, which is connected to the instrument's working-channel for precise laser fiber advancement (Figure 57.9b).

## Experimental evaluation

For all MCC steering, and movement reliability functions, the Avicenna Roboflex was tested in a validated flexible ureterorenoscopy *in vitro* training model (Minnesota University Kidney Model [25]) containing artificial stones. This enabled safe prototype(s) simulations to evaluate key parameters and all device functions. It was also used for hands-on training of all participating surgeons.

### *In vitro* studies

Avicenna Roboflex showed safe, stable maneuverability, with easy translation of MCC functions when in both bench training models and pig ureters. Prototype ergonomics were already good, but incremental improvements to wrist movements, and fine-tuning of deflection were made.

## Surgical technique

With the patient under general anesthesia, supine in lithotomy, intravenous diuretic (lasix) and antibiotic prophylaxis are given, and manual cystoscopy, retrograde pyelography, and placement of a safety guidewire can be performed. The ureteral orifice is accessed with a semi-rigid ureteroscope, inspecting the ureteral lumen up to/beyond the ureteropelvic junction, thereby achieving maximal optical ureteral orifice and ureteral dilation, leaving behind a working wire as needed. A suitable size (10–12/12–14 Fr) and length (35–46 cm) UAS is then advanced into the upper ureter under fluoroscopic control as needed, confirming ureteral integrity postplacement with further pyelography via the access sheath obturator.

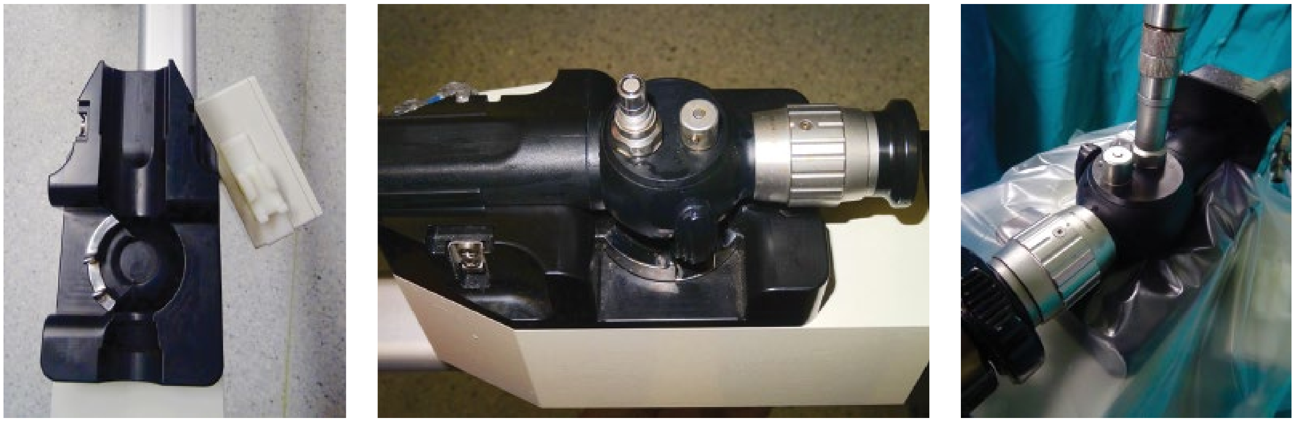

**Figure 57.8** The MA custom endoscope coupler and motorized actuator housing, with FUR hand piece fixed in the manipulator coupler and stabilized by double clip holder after draping.

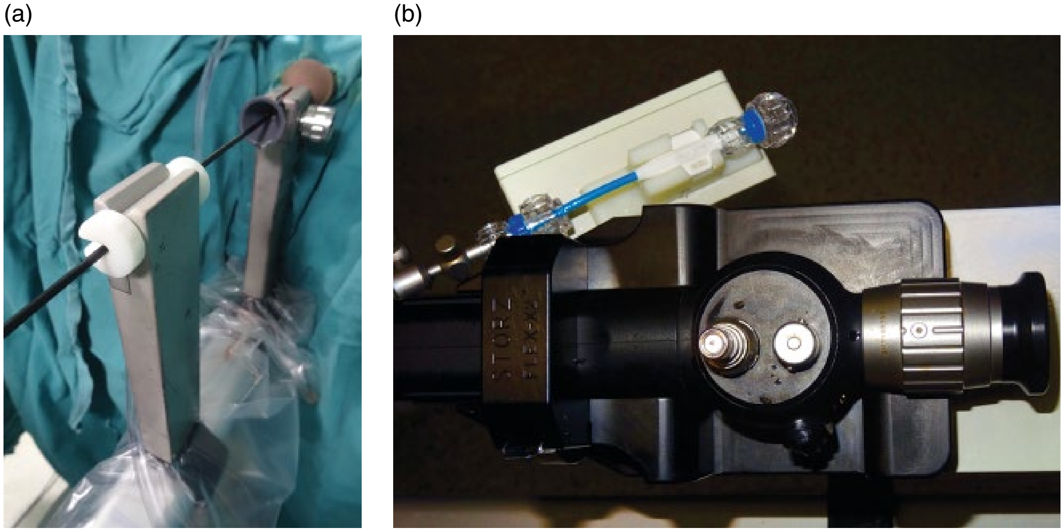

**Figure 57.9** (a) The proximal stabilizer supports the straight endoscope shaft, while the distal stabilizer fixes the UAS shaft in the same plane. (b) The laser fiber (and irrigation tube) is attached to the endoscope by a motorized actuator for fine laser fiber movements.

Next, the FUR is inserted into the UAS lumen and its hand piece is fixed in the sterile plastic-draped robotic-arm coupling adaptor, where it is securely locked with securing clips. Thereafter, checks are made for a stable, secured, straight FUR shaft, before console steering can begin. Using the MCC touch screen and control levers, the target stone(s) is endoscopically visualized and recorded with fluoroscopic snapshot (master console floor left foot pedal). If the laser fiber was not inserted at the start, the endoscope is placed in a neutral straight retracted position with the console zero button to guarantee safe laser fiber insertion without risking work channel damage. The MCC provides a memory function to guide the scope back to its previous position near the stone surface after laser fiber insertion. The inserted laser fiber tip with cladding should be just visible near the endoscope tip and the eye button on the master control laser fiber box is activated for memory entry. Only then can the fiber be retracted to a position level with the scope tip (zero button) and advanced from there by the console touch screen controls using the actuator device fitted to the endoscope work channel. The fiber cannot be retracted inadvertently into the scopes working channel and energy activated, where it might damage the instrument. Once the fiber is advanced (as shown by bicolored bar in MCC laser fiber panel) with precision to the optimal distance from the stone surface, laser-induced lithotripsy can be initiated, ideally "dusting" the stone surface with meandering rotation and small up-and-down deflection movements of the laser fiber tip in the millimeter range using the left hand rotation control lever and/or the right hand pin-wheel control, or by fragmentation (various techniques). Any commercially available holmium:YAG laser unit can be used, but one that allows higher-frequency application at low energy is recommended for optimal dusting. Smaller fiber sizes allow sufficient scope tip deflection with lowest risk of fiber fracture in the work channel at maximum energy and frequency. Once fragmentation has started, higher energy frequency gives a "popcorn effect" for fragment pulverization when dusting is not possible. Sometimes, with fiber tip in the calyx lumen center, this can even be done "hands-free" if time-consuming (see Video 57.1). Fiber tip erosion must be monitored, as it reduces energy transfer over time, and judicious appropriate cleaving with fiber re-introduction is undertaken as required. To introduce nitinol baskets for fragment retrieval at the end, the laser actuator has to be driven back to its preset zero position with the endoscope tip straight, and the fiber exchanged for the basket, once the laser console is on standby (assistant). This might be time-consuming especially if there are multiple fragments, and hence ablation by stone dusting is preferred until a suitably sized fragment is retrieved at the end for stone analysis. The need for JJ stent placement at the end of the procedure is not mandated, but left to the operator's discretion.

## Published clinical experience

### Patients and outcomes

In the first peer-reviewed study, Ankara Medical School ethics commission approval was secured, and 81 patients were treated (IDEAL stage 2) (Table 57.1). Inclusion criteria were aged >6 year, single or multiple stones with a 30 mm total diameter ceiling, absent active urinary tract infection, and no previous ureteral surgery. All patients or minors' parents were informed about Avicenna

**Table 57.1** Baseline RA-RIRS demographic and outcomes data ($n = 81$).

Roboflex use and provided informed consent. Primary end points included RA-RIRS safety and reproducibility based on successful fragmentation data, second sessions, auxiliary measures, complications (Clavien-Dindo classification), and any FUR-related/robot malfunction. Secondary end points were robot docking time, stone location time, fragmentation time, and speed (cubic millimeters per minute) based on computed tomography (CT) stone volume evaluation [27–29], console, and treatment time. Numerical data were expressed as mean with standard deviation (SD) including range; categorical data were expressed as numbers. SPSS v.15 (IBM Corp, Armonk, NY, USA) was used for data analysis. Categorical variables were analyzed using the $\chi 2$ test (or Fisher exact test). The Mann–Whitney U test was used for numeric variables. $P$ values <0.05 were considered statistically significant.

79 patients (97%) had complete stone disintegration. One patient with a large lower calyceal stone (2.5 cm) had intraoperative digital FUR failure (case 42; broken video system); cRIRS conversion did not allow procedure completion due to complicated access plus stone burden, and interval cRIRS was needed 5 days later. Another patient required secondary cRIRS for significant residual fragments. All patients had DJ stents, with removal after a median 7 day interval (range 5–10 days). Three-month stone-free rates were judged by plain X-ray and ultrasound.

## Ergonomics

Based on a published questionnaire comparing laparoscopic and robot-assisted laparoscopic surgical ergonomics [30], the operator's discomfort during RA-RIRS was subjectively compared to their last 10 home institution cRIRS cases. All participating surgeons preferred standing-position cRIRS. A significant difference existed when comparing classic and RA-RIRS ergonomics for all questionnaire domains (Table 57.2; total questionnaire score 31.3 vs. 5.6 respectively; $P < 0.01$).

## Radiation safety

Operating room personnel are at X-ray exposure risk in RA-RIRS (fluoroscopically guided stone procedure). Hence, fluoroscopic radiation exposure was measured during RA-RIRS for patient, anesthesiologist, and urologist, using RANDO phantoms, 19 thermoluminescent dosimeters (TLDs), and 21 TL ring dosimeters (TLRDs). The patient RANDO phantom with upper abdominal TLDs to measure the surface dose was placed on the operating table. The anesthesiologist and surgeon mannequins

were protected (0.5 mm lead apron and thyroid shield), and positioned near the operating table with eye, thyroid, extremity, and gonad region TLDs. The anesthesiologist mannequin was 1 m, the surgeon 0.74–0.8 m, and the Avicenna Roboflex console surgeon was 1.74–2.46 m from the fluoroscopy tube.

Retrospectively reviewed medical records revealed 30 seconds' mean cRIRS fluoroscopic screening time. Mean fluoroscopy tube potential and tube current were 66 kV and 4.99 mA, respectively, and were used to irradiate the RANDO phantom for 10 minutes (600 seconds) corresponding to 20 (600/30) RIRS operations, with a mobile multidirectional C-arm fluoroscopy unit.

In this study, for 600 seconds of fluoroscopic guidance time, the patient surface dose was 1.41 mSv (=70.5 μSv per operation), the anesthesiologist's exposure was 0.1 mSv (=5 μSv per operation), the patient-side surgeon was exposed to 0.11 mSv (=5.5 μSv) for left foot and 0.15 mSv (=7.5 μSv) for right foot. All radiation doses were below the 0.1 mSv (=5 μSv per operation) detection limit for the unprotected surgeon at the Avicenna Roboflex master console. In a urology department where 250 annual RIRS procedures take place, the annual mean dose equivalent for the anesthesiologist and patient-side urologist were calculated to be 1.25 and 1.63 mSv respectively. These preliminary results indicated that patient's and medical professional's radiation doses were quite low, but could be safely eliminated for the Avicenna Roboflex console surgeon without needing any lead protection whatsoever [31]. Self evidently, this has a significant beneficial impact on surgeon comfort and endurance.

### Training study [32]

Five experts and novices were compared in classical versus RA-RIRS for complete stone fragmentation time in five cases. There was a longer average time for RA-RIRS versus cRIRS for experts (28.84 vs. 22.04 min) and vice versa for trainees (29.84 vs. 35.72 min), who were >13 minutes slower than experts in cRIRS. Trainees learned and approached expert RA-RIRS proficiency levels after only four trials in the bench model training setting.

### Flexible ureterorenoscope and manipulator arm durability

Preliminary personal communication data (Dr R. Saglam) suggested that Avicenna Roboflex use at the Medicana Hospital, Ankara, Turkey, coupled to a first-generation Karl Storz Flex-XC yielded a scope durability of 42 cases with the first instrument coupled to early prototypes, and 210 RA-RIRS stone cases thereafter with multiple users, before scope electrical failure occurred in each instance. A dedicated team member plus Cidex sterlization techniques may have both contributed to some of this instrument longevity. Moreover, the second instrument was also used to demonstrate the Avicenna Roboflex at all major urological congresses over 3 years. There has only been one instance of MA malfunction due to water seepage into electronics in early trials, resolved by better custom drapes.

## Discussion

Incremental cRIRS technology improvements over two decades have culminated in dual active endoscope deflection capability, dual-channel digital ureterorenoscopes, hybridized semirigid and coaxial flexible instruments [33], and now disposable/limited-use digital and fiber-optic scopes. Laser fiber technology has also improved with adjustable pulse duration and rounder tips to protect scope work channels better during introduction when new, coupled with a wide array of nitinol stone-retrieval accessories with allied techniques (LC clot [34], blue spritz, etc.). These developments have been actively disseminated by pioneering experts through didactic lectures and hands-on courses, under the aegis of all the major national and international urological societies including the Endourology Society, culminating in widespread cRIRS adoption [35]. Early cRIRS champions and experts have recently tackled more complex intrarenal pathologies, particularly renal stones >1.5 cm, as reflected in updated international European and American guidelines. However, cRIRS is not without its challenges, particularly in these complex cases (e.g. larger stone burden or multiple intrarenal and/or ureteral calculi). Ergonomic problems [36–38] (hand elbow, shoulder, neck, back, hips, knees, ankles) are related to wearing protective lead gowns, thyroid shields, and hand and eye protection in some cases, when performing standing or seated cRIRS on stools for long time periods, leading to operator fatigue. Further challenges include respiratory renal excursion, hindered working space, and the need to simultaneously use various foot pedals to control lasers and/or fluoroscopy equipment, while relying on allied team members to activate laser panel settings and between standby and active settings, or for irrigation adjustments and fluid bag changes, and simultaneously dealing with rapidly changing intraoperative circumstances and fleeting stone treatment opportunities which may influence ultimate success or failure. Together, these lead to cumulative operator fatigue amd physical exhaustion, particularly when treating several such challenging cases of over an hour each throughout the day. This has obvious

**Table 57.3** Summary of cRIRS series in the last decade.

| Study | Year | No. of patients | Stone size (cm) | Mean no. of procedures | % Stone-free rate |
|---|---|---|---|---|---|
| Mariani [39] | 2007 | 16 | ≥4 | 2.4 | 88 |
| Riley [40] | 2009 | 22 | 3 | 1.8 | 90.9 |
| Breda [9] | 2009 | 27 | >2 | 1.6 | 85 |
| Bader [41] | 2010 | 24 | 2.975 | 1.7 | 92 |
| Hyams [42] | 2010 | 120 | 2.4 | ? | 98 |
| Aboumarzouk [43] (meta-analysis) | 2012 | 445 | 2.5 | 1.6 | 93.7 |
| Takazawa [44] | 2012 | 20 | 3.1 (2–5) | 1.4 | 90 |
| Cohen [45] | 2013 | 145 | 2.9 | 1.6 | 87 |
| Miernik [46] | 2013 | 38 | 2.71 | 1.1 | 82 |

detrimental knock-on effects to fine motor skills, task performance, and precision, even in expert hands! This may result in premature termination of a planned procedure, double-J stent placement, and the inevitable consequence of staged treatment to render the patient stone free. This was validated by cRIRS treatment outcomes in expert hands this past decade (Table 57.3).

Consequently, an opportunity to implement mechanically controlled devices into cRIRS procedures was presented. Desai et al. first exploited this opportunity with the Sensei-Hansen Robotic Catheter System, a cardiology/vascular system, adapting it for RA-RIRS, testing it in pigs (one renal pelvic perforation) and then in 18 patients [4, 5] (0.5–1.5 cm renal stones). Their four-component device consisted of a master input device, a dual catheter system with an inner flexible steerable component, a remote inner catheter/manipulation system, and an electronic rack containing computer hardware, power supplies, and video distribution units. The robotic flexible catheter system had a 12/14 Fr outer catheter sheath and inner 10/12 Fr catheter guide. A passive optical fiberscope was inserted through the inner catheter guide lumen. Remote catheter system manipulation maneuvered the flexible fiberscope tip, glued in place within the inner guide. The larger outer sheath tip, positioned at the ureteropelvic junction to stabilize the inner navigation guide within the collecting system, allowed passenger fiberscope manipulation within the inner catheter guide. Of 18 patients only three minor complications (transient fever in two and limb paresis in one), three secondary PCNL for stone residual, and 89% 3 month CT excretory urogram stone-free rate were reported. This device has since been discontinued in urology.

The Avicenna Roboflex robotic system was developed to be specifically dedicated to RA-RIRS. It has tackled many of the ergonomic challenges of cRIRS. After a proof-of-concept phase [25] (IDEAL stage 1) and progression from prototype to working design (IDEAL stage 2a), Saglam et al. demonstrated safe, efficacious device deployment, with a short learning curve, and disseminated the technology among selected experienced endourologists with varying cRIRS expertise (IDEAL stage 2b), publishing data from the first seven's early cases (Table 57.1). RA-RIRS performed in a comfortable ergonomically sound seated position remote from the operating table eliminated the drawback of surgeon (±assistant) fatigue from prolonged standing between the patient's legs at the operating table. Additionally, the surgeon doesn't need to wear protective lead items, for the Avicenna Roboflex MCC surgeon seat can be parked at a suitable safe distance from the operating table as our preliminary studies have shown [31]. The cumulative benefits of these ergonomic stress relieving RA-RIRS aspects was subjectively scored by initial users in Saglam et al's *European Urology* publication [26], and reported significant superiority over cRIRS, a finding verified by this author's current personal series of 17 cases.

The robotic MA enhances and directly drives all mechanical FUR functions, providing a further level of external control beyond the inherent endoscope mechanics, but does not eliminate disadvantages inherent to the FUR deflection cable-drum design mechanism, leading to slightly lagged responses in fine up-and-down tip deflection. Custom-made endoscope hand-piece couplers (different for each manufacturer's scope model) can be made, (an advantage) and are attached directly to a specially designed master plate of the robotic MA. The hand-piece deflection lever is moved by computer-controlled micromotors in the coupler, which communicate with the MCC unit via a cable connector. The RA manipulator also enables two-point shaft stabilization, allowing safe bidirectional rotation, plus advancement and retraction of the fixed instrument hand piece. Thus, RA-RIRS can be performed using standard 10–12 or 12–14 Fr variable length UAS, although shorter length/wider lumen is preferred to allow maximum deflection and dust efflux at the lowest pressures. All endoscope movements can be fine-tuned and scaled to adjustable degrees through the MCC. This level of control is not possible manually in a sustained manner in cRIRS. The laser fiber actuator allows fine motorized forwards and backwards movements beyond the endoscope tip without moving the endoscope itself, with automatic repositioning to a baseline neutral position where it cannot damage the endoscope tip. This lends further operator-controlled precision to stone dusting performance, fragmentation, and ablation, by allowing the operator to maintain the optimal distance between fiber tip and target to maximize the photo-acoustic pulsed stone surface ablation without having to adjust the scope tip position every time. Tables 57.4 and 57.5 describe and compare the ergonomic demands of cRIRs to RA-RIRS.

A key goal for introducing surgical master/slave robotic devices is to reduce the cumulative surgical ergonomic stresses of long and arduous cRIRS procedures for complex and large renal stones. A comfortable environment potentially augments an individual surgeon's capabilities, improves quality and throughput, and provides a comfortable learning environment for the less experienced urologist/trainee endourologist. Hand/wrist/other ergonomic problems reported in up to one-third of endourologists were re-iterated by Saglam et al. [26]. Avicenna Roboflex provided a comfortable platform that significantly improved ergonomics after a short learning curve (subjective score 5.6 vs. 31.3, $P < 0.01$). The fatigued surgeon translates to higher complication rates, longer operating times, additional treatment sessions, and frequent repair of delicate expensive FURs.

Carey et al. [47] reported new FUR damage-repair rates of 8.1% (6% unusable) at a single tertiary center after 40–48 uses, mainly due to errant laser firing (36%) and excessive instrument torque (28%). In our own evaluation, cRIRS instrument durability in a tertiary referral center was increased to >100 cases [48] by using the semirigid instrument as the workhorse and having the FUR tip occupied by a laser fiber in full deflection mode for the shortest possible time. However, initial experience reported here by Saglam (personal communication), if verified by others, suggests much greater scope longevity in RA-RIRS compared to cRIRS. The Avicenna Roboflex design, requiring laser fiber insertion only in a straight scope position using a console based memory function, stepwise motorized advancement of the laser fiber, and force-controlled (maximal $1\,\text{N/mm}^2$) deflection of the scope with similar controlled rotation of the supported torque-free shaft outside the UAS, are just some of the features that should contribute to potential FUR longevity (partially offsetting robot costs cumulatively).

Possible Avicenna Roboflex limitations are current lack of tactile feedback (as with all master/slave robotic devices),

**Table 57.4** Ergonomic demands of cRIRS.

| Operative action | Extremity(ies) required | Performed by |
|---|---|---|
| FUR insertion | Fingers of both hands (at glans-access sheath hub, and FUR handpiece) | Surgeon |
| FUR deflection | Hand holding handpiece and thumb deflection lever; fingers of other hand at meatus-access sheath hub to maintain straight shaft for optimal deflection capability | Surgeon |
| FUR rotation | Hand-holding hand piece; fingers of the other hand rotating shaft at meatus | Surgeon |
| Fluoroscopy activation | Hand/foot | Radiology technician or certified surgeon |
| Multifunctional operating table or C-arm movement | Arms/hand, foot, and torso | Radiology technician or certified surgeon |
| Irrigation control | Thumb and hand | Nurse or assistant |
| Syringe (contrast-flush-aspiration) | Thumb and hand | Surgeon |
| Nitinol accessories insertion or activation | Thumb and index finger(s) | Surgeon |
| Laser fiber insertion, advancement, and retraction | Thumb and index finger | Surgeon |
| Laser settings | Index finger | Nurse or assistant |
| Laser ready, standby modes | Index finger | Nurse or assistant |
| Laser activation | Foot | Surgeon |

**Table 57.5** Comparing control of cRIRS and RA-RIRS.

| Feature | cRIRS | RA-RIRS |
|---|---|---|
| Surgeon's position | Standing between patient legs in lithotomy | Seated comfortably with arm rest at MCC |
| FUR insertion | Manually through UAS | Manually through UAS |
| FUR advancement, rotation | With both hands | MCC joysticks (2) |
| Fine regulation of deflection | Not available, manual attempt | MCC right joystick pin wheel |
| Laser fiber insertion | Manually through working channel | Manually through working channel |
| Laser fiber fine movements in and out | Manually through working channel | MCC touch screen control |
| Laser activation in ready mode | Foot pedal (standing), not fixed to floor by operating table | Red foot-pedal control (sitting), fixed to MCC floor (right) |
| Laser energy/frequency, standby/active mode adjustment | Manually at device | Manually at device |
| Fluoroscopy activation | Hand/foot pedal control, radiographer | White foot-pedal control (sitting), fixed to MCC floor (left) |
| Table or C-arm movement | Manually, anesthetist/radiographer | Manually, anesthetist/radiographer |
| Irrigation control | By irrigant bag height (nurse) and/or surgeon-controlled pump (syringe, hand or foot pump) | MCC touch screen control |
| Nitinol accessories, insertion/activation | Manually at scope work channel | Manually at scope work channel |

underpinning the enduring need of a certain degree of surgeon expertise using compensatory visual clues and precisely controlled movements, and spatial awareness of the scope in all three dimensions. This will change in the future as haptic feedback technology evolves, but is not as critical in RA-RIRS as compared for laparocopic surgery, as the FUR coupled to the MA is introduced and advanced up the ureter inside the lumen of a ureteral access sheath. Additionally, there is the issue of the two-dimensional image monitor screen for scope tip navigation, and problems with the continued need to use baskets for stone fragment extraction where dusting or pop-corning is not possible. Although some have debated whether cRIRS should aim at complete stone ablation by dusting, or whether larger fragments should be actively retrieved using a nitinol basket via the UAS, the need for the latter should be minimal except for harder large stones once fragments are sub-5 mm or in high frequency recurrent large stone formers with uncorrected underlying metabolic risk factors, thus avoiding the need for time consuming partial undocking from the MA shaft support feature. Finally, the device cost may become a significant issue, particularly with respect to financial restrictions of healthcare systems in austerity. Following the IDEAL framework, a multicenter multinational prospective randomized controled trial should be planned to provide more specific details about the potential advantages of RA-RIRS versus cRIRS and smaller access PCNL techniques, for medium–large or branched renal stones, using CT-based end points for stone-free rates.

Presently, of over 4000 companies, 150 have a market cap of > US$200 million, with $2 billion worth of mergers and acquisitions, and $1.3 billion equity funding in the robotics sector of the global economy, with Japan leading the way. Most of this investment is dominated by civilian drone technology, with a 122% compound annual growth rate for 3D printing, and 36% industrial robotics growth in China alone between 2008 and 2013.

As surgeons, we need the surgical tools of tomorrow, not as replacements for ourselves, but as a means to enhance our individual abilities in order to be our best selves without fear of fatigue, so as to deliver superior patient outcomes. With this in mind, many have asked if they really need an expensive tool such as a robotic device? The lab data perhaps suggest not, but the answer must surely be … only if it can deliver patient outcomes that are worth the premium price or ultimately lead to other cost savings (shorter operating time, lower operating room support personnel requirement, lower complication rates [intra-and postoperative], less operator fatigue leading to lower retreatment rates, less FUR breakage, shorter operating room times per stone volume unit disintegrated, for a given stone hardness, location, and collecting system configuration, and lower auxiliary procedure rates). Ideally, it should allow us to tackle bigger stones in difficult places in the urinary tract without making painful holes [49] or risk bleeding, improving on current stone-free rates, and still be able to send patients home safely in minimal discomfort the same day without fear of re-admission or retreatment.

New technology is “new” but never born perfect out of engineering development! After birth, it must pass through an evolutionary and clinical refinement process driven by a cadre of key experts collaborating with the engineering brains, by using it over a realistic time period in real-world settings, based on complexity and learning curve issues. During this time, views are often polarized, sometimes perjoratively depending on how it is presented and who the early adopters are. Nevertheless, it generally creates public awareness, which leads to excitement and debate, especially (as seen with the Da Vinci), when marketed directly to patients and providers by organizations with vested interests. Thus at a time of increasing healthcare consumption, bottlenecks, and fiscal constraints, any new technology must ultimately prove its worth rather than being just another example of fulfilling the prophecy of “the emperor’s new clothes” [50]. This means that for all technology, there are price points for affordability and cost-benefit to be considered. To underpin these, there must be a high-quality evidence base. Currently, Avicenna Roboflex RA-RIRS is somewhat limited by two factors: current FUR design and ureteral lumen size for access and fragment removal. So with RA-RIRS we must ask ourselves, will this tool extend what we as expert surgeons can do for our patients today or in the near future? Does it enhance their, our, or our team’s safety? Does it have future development potential and versatility inside of and beyond the urological specialty? And is it future-proofed for modifications that could lead to improved performance for a reasonable time period to make the high initial investment outlay viable? Will most people be able to afford it eventually? Will it allow acquisition of advanced skill sets across a wider spectrum of practitioners, trainees, and novices, and can these be honed to perfection outside the clinical working environment, or is it just another very expensive comfortable chair?

The answers to these questions will vary from unit to unit, and will depend on many factors such as skill sets and referral patterns. For example, you don’t need Avicenna Roboflex if the majority of ureters you deal with will not readily accept a UAS, or the majority of stones you treat are large branched hard renal stones where PCNL may still be arguably superior! However, if one’s goal is to maximize the control a surgeon has over their endourological working environment and potentially increase it in the future, improve ergonomics to reduce fatigue and allow increased quality and throughput other factors notwithstanding, reduce the need for invasive painful percutaneous surgical procedures in an increasingly elderly and obese population dynamic, afflicted by comorbidities and needing blood-thinning medications, in whom stone disease is increasing and has a higher recurrence rate, then RA-RIRS should certainly be a mouth-watering prospect. This is especially true in a training center with a tertiary referral practice of sufficient volume, where young surgeons are increasingly challenged in skills acquisition and transfer by reduced working hours. Together, they may provide a strong argument for expensive technology to be limited to regional centers to begin with.

Moreover, it certainly is a potential asset where endourological precision is key such as in the renal conservative management of upper urinary tract urothelial cancer, where this author has undertaken the first RA-RIRS case to date (see Video 57.1), or complex stone disease with reduced renal function that needs to be preserved to avoid dialysis, or for those at significant risk of bleeding complications (multiple puncture PCNL in high risk patients on blood thinning or antiplatelet medications that cannot safely be discontinued). Moreover, if by simply changing a coupling adaptor, the device becomes a flexible multispecialty tool, it has the potential for real cost-effectiveness and becomes a viable part of the future hospital landscape beyond urology. Our young successors may be much safer (with regards to the long-term consequences of cumulative radiation exposure) and proficient much faster than this endourologist generation [32]. The heavy burden of wearing lead protection for the whole duration of our careers, with long-term impact on our vertebrae and attached musculature will finally be shed.

With surgical robotics, we are not yet at the stage where we have self-learning programmable autonomous systems like the proverbial autopilot that can fully operate aircraft from take off to landing. Will we ever want this in the human body shop? Only time will tell, depending on where processor and biosensor functions along with machine learning, drive us as physicians and surgeons. What is clear is that we are at the beginning of a global social robotic revolution and the future may bring us hybrid machines possessing ambient intelligence, which can bring lasting value to surgical procedure outcomes. Human empathy and creativity may be the last bastion against the rule of artificial intelligence. Quintessentially, human roles in medical care can be enhanced, leaving individuals with more time to care, teach, create, and innovate, by embracing technology and innovatively shaping it to human needs. The future is exciting indeed!

## Acknowledgments

In the preparation of this chapter I am deeply indebted to Dr Remzi Saglam and Mr Sinan Kabakci for assistance in providing some historical figures, key aspects of unpublished information, and video-editing assistance.

## Introduction

Since its inception in the early 1980s shock-wave lithotripsy (SWL) has become the treatment of choice for the majority of urinary stones because of its non-invasiveness compared to traditional stone treatments [1–3]. In the early 1990s more than 85% of stone patients in Europe and the United States were treated with SWL [4]. Although this trend has been in decline since then because of the rapid advance in endourological technology and technique, still about 70% of kidney stone patients in 2002 and fewer than 50% in 2005 were managed by SWL [2, 4–6].

A primary factor that has contributed to this gradual decline in the clinical use of SWL is the reduced treatment efficiency, compounded by the increased retreatment rate and higher risk of tissue injury produced by the second- and third-generation lithotripters, compared to the first-generation HM3 lithotripter [7, 8]. Although SWL technology has evolved significantly over the past two decades, there is still debate regarding the physical basis and clinical benefits of technical modifications such as the tight focal width and high peak pressure fields often used in many contemporary lithotripters [9–11]. Better design as well as effective and safe use of shock-wave lithotripters must rely on a clear and fundamental understanding about the physics of this innovative technology.

The physics and acoustical principles of SWL have been reviewed previously [12–14]. This chapter will therefore focus on the most salient features of SWL physics that are relevant to understanding the mechanisms of stone comminution and tissue injury with emphasis on contemporary technologies. The materials in this chapter are condensed in acoustics and physics content from a recent review of the topic by the senior author [15], but otherwise expanded based on the latest studies in order to provide a guideline for better lithotripter design, and effective and safe clinical use of this non-invasive technology for stone management.

## Overview of the clinical goal and physical process in SWL

The overarching goal of SWL is to pulverize kidney stones into gravels for spontaneous discharge in urine without inflicting adverse effects to surrounding tissues. As illustrated in Figure 58.1, disintegration of kidney stones by focused shock waves is a progressive process in which fragments of different size, shape, and distribution in the renal collecting system will be produced that may all influence the clinical outcome. In particular, the rate of stone comminution is not uniform throughout SWL. Stone disintegration accelerates initially within a few hundred shocks, followed by a gradually decelerating process towards the end of treatment. This critical observation suggests that different mechanisms of stone fragmentation may exist during the course of SWL, a unique feature that was not taken into account in the design of the second- and third-generation lithotripters. To succeed in SWL, it is important to gain a fundamental understanding about acoustic waves (Box 58.1), the characteristics of focused shock waves produced by lithotripters (Box 58.2), and the physical basis for the optimal selection of lithotripter parameters and treatment protocol (or strategy) to maximize stone comminution while minimizing tissue injury.

**Box 58.1 Basics of acoustic waves [12].**

An acoustic (or sound) wave is a form of mechanical vibration that propagates within a fluid (either gas or liquid). The wave locally compresses the fluid particles, i.e., the molecules are forced closer, pushing against each other. Compression in one region is accompanied by rarefaction (or tension) of the fluid particles in the adjacent region due to conservation of mass. This alternating vibration of compression and tension leads to the formation of a "wave" that travels through the fluid. The speed of wave propagation (referred to as the sound speed) is a material property of the medium, which is about 340 m/second in air, and about 1500 m/second in water and most soft tissues of the body. Notably, individual molecules of the medium do not travel with the acoustic wave; rather they just jostle adjacent molecules. Therefore, the medium serves as a carrier for the acoustic wave to propagate. This is an important physical distinction between mechanical waves (e.g., acoustic waves, water waves, elastic waves in solids) and electromagnetic waves (e.g., light waves, radio waves, X-rays). For electromagnetic waves energy is carried by photons, which may be thought of as particles that physically travel through space without the need of a carrier medium. For example, light can travel through a vacuum; in contrast, sound cannot.

## General principles of shock-wave lithotripsy

All clinical lithotripters are constructed using four primary components: (i) shock-wave generator, (ii) focusing device, (iii) coupling medium, and (iv) stone localization system. The original Dornier HM3 lithotripter employed a water tub for coupling to ensure effective transmission of the lithotripter-generated shock wave (LSW) without significant loss of energy at the patient's surface (Figure 58.2a). In contrast, for operation convenience all contemporary lithotripters use dry coupling modalities with a water cushion system (such as the Siemens Lithoskop shown in Figure 58.2b). Three primary types of shock-wave lithotripters have been developed – electrohydraulic (EH), electromagnetic (EM), and piezoelectric (PE) shock sources – with a variety of focusing systems (Figure 58.3). Stone localization in modern lithotripters is performed using isocentric C-arm fluoroscopy with optional inline or offline ultrasound imaging [3]. The combination of the shock-wave generator and the focusing device determines the main characteristics of the lithotripter field.

### Shock-wave generation

In EH lithotripters, a spherically divergent shock wave is generated by a high voltage (12–30 kV) discharge between

### Box 58.2 Basics of lithotripter-generated shock waves.

Several different approaches have been used to model the shock-wave propagation and focusing in a lithotripter [19–21]. Majority of the models use the Euler equations for compressible fluids, in combination with the Tai equation of state for water shown below:

$$p = B\left[\left(\frac{\rho}{\rho_0}\right)^n - 1\right] \tag{1}$$

where $p$ and $\rho$ are the pressure and density of water immediately behind the shock front, $\rho_0$ is the density of water under ambient conditions, $B$ (= 3000 bars) is a characteristic constant, and $n = 7.15$ [22]. It can be shown based on conservation of mass and momentum analysis that the Mach number at the shock front ($M_s = c/c_0$; where $c$ is the speed of the shock front and $c_0$ is the sound speed in water under ambient conditions) is determined by [14]:

$$M_s^2 = \frac{r}{n}\frac{r^n - 1}{r - 1}, \text{ with } r = \frac{\rho}{\rho_0} \tag{2}$$

Considering that positive peak pressure $p+$ in a lithotripter field is usually below 100 MPa, equations (1) and (2) indicate a density ratio below 1.05 and a Mach number less than 1.09 across the shock front of typical lithotripter-generated shock waves (LSWs). As a LSW approaches the lithotripter focus, a Mach stem will be formed, leading to a planar shock front followed by diffracted waves originated from the aperture of the shock-wave source [14, 23].

LSW can be significantly attenuated when propagating through interposing skin and soft tissues to reach the kidney stone. Although the pulse profile of the LSW remains similar, there is about 30% reduction in $p+$ with a concomitant threefold increase in the rise time of the shock front and 44–67% broadening of the focal width from *in vitro* to *in vivo* [24]. Thermal effects in SWL are negligible. In clinical SWL, a pulse repetition frequency (PRF) of ≤ 2 Hz is typically utilized. However, even at a PRF of 100 Hz, the accumulated temperature increase produced by a clinically relevant shock-wave exposure was estimated to be less than 2 °C [25]. Therefore the interaction of LSWs with biological tissues and renal calculi is primarily through nonthermal mechanical effects.

In comparison, electromagnetic (EM) and piezoelectric (PE) lithotripters have a larger dynamic range in pressure output, longer lifetime of the shock source, and more stable output than electrohydraulic (EH) lithotripters. Clinically, EM and EH lithotripters are more commonly used because of their broader focal width in combination with the higher effective acoustic pulse energy produced than PE lithotripters [9, 26]. Low energy output compounded with narrow focal width of the PE lithotripters result in longer treatment time, making them less favorable in high-volume stone clinics [10, 27]. The primary field parameters of different types of lithotripters are summarized in Table 58.1.

the tips of an electrode, which vaporizes and expands supersonically the surrounding fluid. In EM lithotripters, a magnetic field is produced by applying a high voltage (8–20 kV) pulse to a coil in flat, cylindrical, or spherical configuration to inject a strong current into the coil that repels an adjacent thin metallic membrane (in which a counter current is induced) to launch a high-amplitude acoustic wave into the surrounding fluid. In PE lithotripters, a high-voltage (1–10 kV) pulse is applied simultaneously to a mosaic of hundreds to few thousands piezoceramic elements that are mounted on a spherical carrier to generate a strong converging acoustic wave towards a common focus. Shock waves in EM and PE lithotripters are formed by nonlinear wave propagation in the coupling medium or interposing soft tissues between the shock source and the lithotripter focus [13].

## Shock-wave focusing

Different designs of acoustic reflector and lens have been utilized for shock-wave focusing. In EH lithotripters, the spark-generated shock wave (at $F_1$) is focused by a truncated ellipsoidal reflector to the second focus ($F_2$) of the ellipsoid where the kidney stones are aligned under imaging guidance. In majority of EM lithotripters, either an acoustic lens or parabolic reflectors are used (Figure 58.3). In PE lithotripters, self-focusing ensured by the geometrical configuration of the shock-wave source is typically utilized. Self-focusing is also employed in a recently developed EM lithotripter by Eisenmenger et al. [16].

## Lithotripter-generated shock-wave profile and distribution

Representative shock waves measured at the focus of the three different types of lithotripters are shown in Figure 58.4. A fiber-optic probe hydrophone (FOPH) [17] recommended for lithotripter output characterization by the IEC standard is often used for such measurements [18]. All shock waves at the lithotripter focus consist of a leading shock front with a positive peak pressure ($p+$) of 40–70 MPa (1 MPa is about 10 times the atmospheric pressure) and an associated compressive

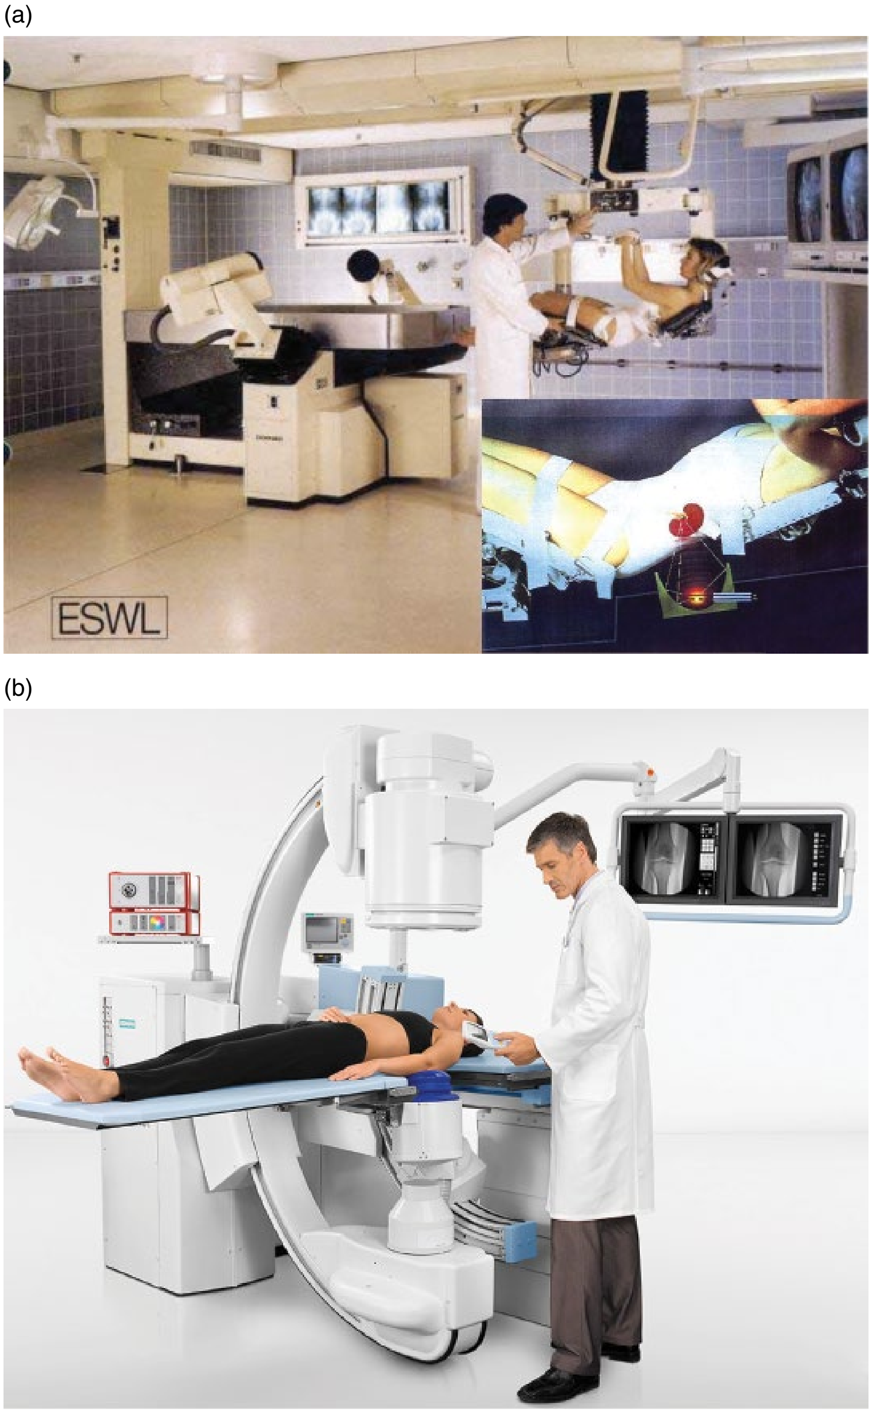

Figure 58.2 Shock-wave lithotripters: (a) first-generation Dornier HM3 and (b) third-generation Siemens Lithoskop. *Source:* from [15] with permission of Springer-Verlag, Berlin, Heidelberg.

wave of 1–2 microseconds in duration (1 microsecond = 1 millionth of a second). This fast rise of the compressive wave is referred to as “shock.” After falling to zero there is then a region of tensile wave lasting about 3–5 microseconds in duration with a peak negative pressure ($p-$) about −10 MPa. The entire shock-wave pulse duration varies from 5 to 10 microseconds. Shock waves are broadband acoustic waves with a fundamental frequency in the range of 150–800 kHz (Figure 58.4a inset) [13]. As depicted in Figure 58.4a there is a notable pressure oscillation after the tensile wave produced by EM and PE lithotripters but not in EH lithotripters. In contrary to EH lithotripters in which the rise time of the leading shock front is less than 30 ns the shock-wave rise

time is about 100 ns for EM and PE lithotripters [13]. In general, pressure amplitudes are machine- and output-setting-specific, and the values of $p+$ can vary from 20 to 120 MPa and $p-$ from −4 to −15 MPa (see Table 58.1).

Limited aperture size of the shock source causes the pressure field to be elongated along the central axis of the lithotripter to form a so-called "cigar-shaped" focus (Figure 58.4b). The size of the lithotripter focal region is measured by the −6 dB focal width (i.e., the dimension in which the positive pressure is equal or above half of $p+$) along the longitudinal and transverse axis of the lithotripter, respectively. It should be noted that the focal width is only a measure of the tightness of the pressure concentration in a lithotripter field. In general, the focal width may not be equated to the dimension of the fragmentation zone in a lithotripter field.

## Composition and physical properties of kidney stones

To understand the mechanisms of stone fragmentation some basic features of kidney stones need to be considered. Kidney stones vary substantially in their chemical composition and structure. Stones are about 95%

**Table 58.1** Characteristics of different type of shock-wave lithotripters.

| Lithotripter type | | C (nF) | V (kV) | Focal length (cm) | Aperture angle (°) | $p+$ (MPa), typical/max | $p-$ (MPa) | $t_r$ (ns) | $t+$ (μs) | $t-$ (μs) | Focal width (mm) | $E_{12\text{mm}}$ (mJ) |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| EH | | 20–200 | 12–30 | 13–17 | 60–80 | 20/80 | −8 to −10 | <30 ns | 1–2 | 4–6 | 8–17 | 20–70 |

aggregated crystalline substances by weight, which are bound by cellular matrix proteins [28, 29]. As depicted in Figure 58.5 the composition of a kidney stone can often change from the core to the shell, as revealed by micro-computed tomography (CT) images [30]. Calcium oxalate monohydrate (COM) or dihydrate (COD) stones represent the most common kidney stones. Other prevalent compositions include calcium hydrogen phosphate dihydrate (or brushite), carbonate-apatite (CA), magnesium ammonium phosphate hexahydrate (MAPH or struvite), uric acid (UA), and cystine. It has been observed that the fragility of kidney stones during SWL varies significantly with composition and structural heterogeneity [31–33].

Table 58.2 summarizes the acoustic and mechanical properties of kidney stones of different compositions, together with their counterpart values in artificial kidney stones that are often used in research to understand the mechanisms of stone fragmentation, and for comparisons of different lithotripters and treatment strategies.

## Mechanisms of stone fragmentation in SWL

Stone fragmentation in SWL is the direct consequence of shock-wave–stone interaction, which is illustrated in Figure 58.6 by high-speed photoelastic and shadowgraph imaging [34]. When a LSW strikes on the stone surface, part of the wave will be reflected back into the water while the other part will be refracted (or transmitted) into the stone. In general, the wave refraction at a fluid/solid boundary will produce two types of stress wave in the solid. One is called the longitudinal (or P) wave, in which the solid particles vibrate in the same direction as the wave propagation. The other is called the transverse (or S) wave, in which the solid particles vibrate perpendicular to the direction of the wave propagation. The acoustical principles of wave reflection and refraction at fluid/solid boundaries are described in Box 58.3. In addition, cavitation – the

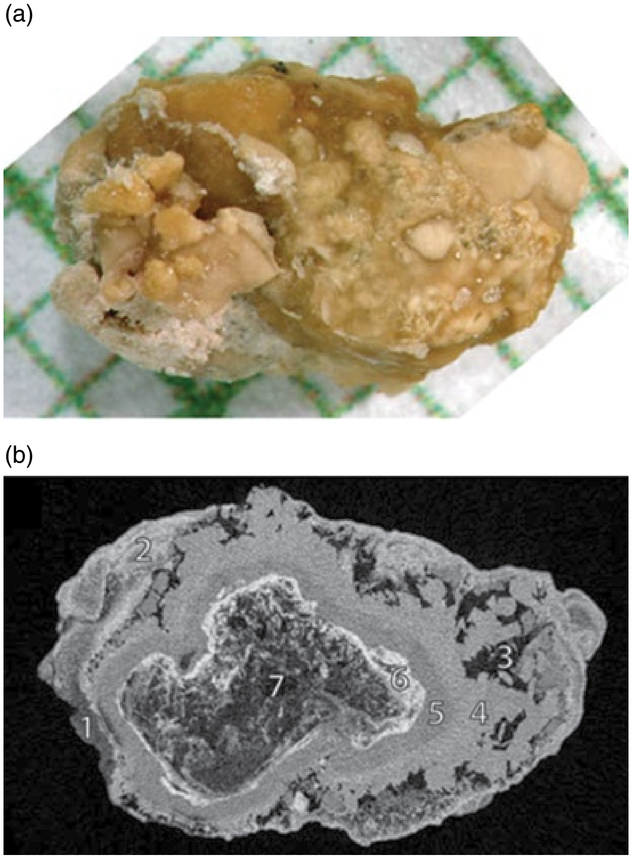

**Figure 58.5** Example of the complexity of mineral regions revealed by micro-computed tomography (CT). (a) Photomicrograph of stone on millimeter grid paper; (b) micro-CT slice through the same stone. Minerals appear to be quite varied, as judged by morphology and X-ray attenuation; e.g., there is a low-attenuation region on the stone exterior (labeled 1) that is distinct from the high-attenuation shell surrounding the stone (2). Beneath that shell are some regions that appear to be void of mineral (3), interspersed among crystalline extensions of an evenly absorbing material (4); inside there is a layer that absorbs X-rays less well (5), which is in turn lined by a highly absorbing mineral (6); finally, the innermost region of the stone (7) is filled with a low-absorbing material that could be subdivided into two or more morphologies. *Source:* from [30] with permission of Springer-Verlag, Berlin, Heidelberg.

formation, expansion, and collapse of gas/vapor bubbles in liquids – will be generated by the tensile component of the LSW, which plays an important, yet different, role in stone comminution and in tissue injury.

Figure 58.8a illustrates the partition ratio in energy flux density of an incident LSW into a reflected pressure wave in water and refracted P and S waves in the solid at different incident angles for six types of kidney stones.

**Box 58.3 Acoustics of wave reflection and refraction at fluid/solid boundaries.**

Figure 58.7 illustrates several general scenarios of wave reflection and refraction (or transmission) at fluid/stone boundaries that are relevant to SWL. The directions of the reflected pressure wave ($P_r$) in the fluid, and the transmitted P and S waves into the solid are determined by the Snell's law:

$$\frac{\sin\theta_i}{c_0}=\frac{\sin\theta_r}{c_0}=\frac{\sin\theta_P}{c_P}=\frac{\sin\theta_S}{c_S} \tag{3}$$

where $\theta_i$, $\theta_r$, $\theta_P$, and $\theta_S$ are the incident and reflected angles of the pressure waves in the fluid, and refracted angles of the P and S waves in the solid; $c_0$, $c_P$, *and* $c_S$ are the wave speed in water, and P and S wave speeds in the solid, respectively. The mode conversion from pressure wave in water into P and S waves in the solid is ensured by the boundary conditions (i.e., continuities of displacement and stress [force per unit area] along the surface normal direction of the boundary). In general the reflection coefficient of the potential for the pressure wave in water ($R$), and transmission coefficients of the potentials for the P and S waves ($T_P$ and $T_S$) in the solid depend critically on $\theta_i$ and are given by: [35]

$$R=\frac{Z_P cos^2 2\theta_S+Z_S\sin^2 2\theta_S-Z_o}{Z_P cos^2 2\theta_S+Z_S\sin^2 2\theta_S+Z_o} \tag{4.1}$$

$$T_P=\frac{2\left(\dfrac{\rho_0}{\rho_s}\right)Z_P cos 2\theta_S}{Z_P cos^2 2\theta_S+Z_S\sin^2 2\theta_S+Z_o} \tag{4.2}$$

$$T_S=\frac{-2\left(\dfrac{\rho_0}{\rho_s}\right)Z_S\sin 2\vartheta_S}{Z_P\cos^2 2\vartheta_S+Z_S\sin^2 2\vartheta_S+Z_0} \tag{4.3}$$

where $\rho_s$ is the density of the solid, and the acoustic impedances (i.e., the product of medium density and wave speed) for the oblique incident pressure wave in water ($Z_0$), and refracted P and S waves in the solid ($Z_P$ and $Z_S$) are given by:

$$Z_0=\frac{\rho_0 c_0}{cos\,\theta_0},Z_P=\frac{\rho_s c_P}{cos\,\theta_P},Z_S=\frac{\rho_s c_S}{cos\,\theta_S} \tag{4.4}$$

When $\theta_i$ exceeds the critical value for total refraction of the P wave (i.e., $\theta_P=90°$) in the solid, only an S wave will be produced in the solid until $\theta_i$ reaches the critical incident angle for total refraction of the S wave in the solid. Thereafter, head waves (H) emanating into both the fluid and solid, and surface acoustic waves such as leaky Rayleigh wave and Scholte wave may be produced at the fluid/solid boundary [15].

The ratios of the normal components of the energy flux density (or intensity) of the reflected pressure wave in water ($I_r$), the transmitted P and S waves in the solid ($I_P$ and $I_S$) with respect to the corresponding value of the incident pressure wave in water ($I_i$) can be determined by [35]:

$$\frac{I_r}{I_i}=|R|^2,\frac{I_P}{I_i}=\frac{\rho_s\tan\theta_0}{\rho_0\tan\theta_P}|T_P|^2,\frac{I_S}{I_i}=\frac{\rho_s\tan\theta_0}{\rho_0\tan\theta_S}|T_S|^2,$$
$$\text{with } I_r+I_P+I_S=I_i \tag{4.5}$$

The last equation in (4.5) indicates energy conservation for wave reflection and refraction at a fluid/solid boundary.

The most striking feature is the broad range of incident angles (after the critical incident angle of the P wave is reached) in which strong shear waves are generated in the stone. In particular, soft stones such as MAPH, UA, and CA can more efficiently convert shock-wave energy into shear over a broad range of $\theta_i$ (26–90°) than hard stones such as cystine, COM and brushite in a narrow range of $\theta_i$ (19–56°). In contrast, the generation of P wave is limited in a small range of $\theta_i$ up to 19–33°, with hard stones possessing lower energy transmission efficiency than soft stones. Moreover, it has been shown that the convergence of the shear waves from the stone boundary into the central region, combined with focusing upon S wave reflection from the lateral and posterior surfaces of the stone leads to the generation of the maximum tension inside the stone (Figure 58.8b) [36]. Multiphysics modeling in COMSOL has confirmed this general feature of LSW–stone interaction (Figure 58.8c). Quantitatively, the modeling results have demonstrated that higher maximum tensile stress ($\sigma_T$) is produced in soft stones such as UA ($\sigma_T=193$ MPa) than hard stones such as COM ($\sigma_T=149$ MPa) under the same lithotripsy condition ($p+=46$ MPa). Similarly, the maximum tensile strain ($\varepsilon_T$) is also higher in UA ($\varepsilon_T=280\times10^{-3}$) than COM ($\varepsilon_T=75\times10^{-3}$) because UA has much lower elastic moduli than COM (see Table 58.2). These results are consistent with the clinical observation of stone fragility in SWL [37].

## Basic concepts of fracture mechanics

Two important concepts in fracture mechanics need to be appreciated in order to understand the mechanisms of stone fragmentation in SWL. First, kidney stones, like other brittle materials (which are fragile under tension or shear), have pre-existing flaws (e.g., defeats, voids, interfaces, cracks; see Figure 58.5). Second, when kidney stones are subjected to the dynamic loading produced by

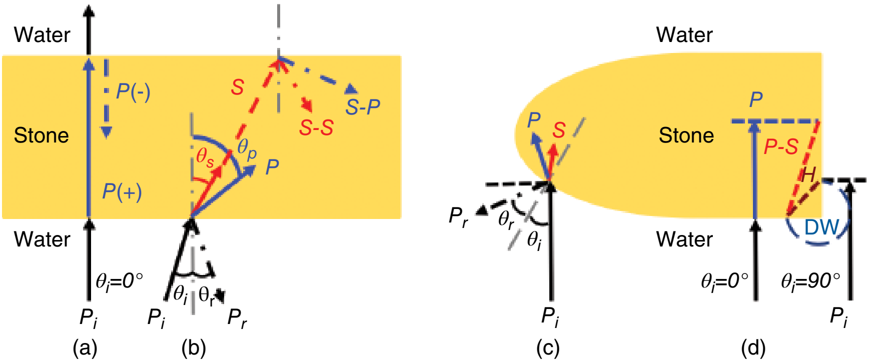

**Figure 58.7** Shock-wave reflection and refraction (transmission) at the fluid/solid boundary. Left: shock-wave incidence on a stone of flat surfaces, (a) zero incident angle ($\theta_i = 0°$) and (b) at an oblique incident angle ($\theta_i > 0°$). Right: shock-wave incidence on a stone with curved surfaces and sharp corners, (c) at an oblique incident angle ($\theta_i > 0°$) on a curved surface and (d) wave diffraction at a sharp corner when the incident angle changes abruptly from $\theta_i = 0°$ to $\theta_i = 90°$, leading to generation of strong shear wave (*P*–*S*) and head wave (*H*) near the lateral boundary of the stone. In water, $P_i$ and $P_r$ denote incident and reflected pressure wave, DW indicates diffracted wave. In stone, *P* indicates longitudinal (or *P*) wave, *S* denotes transverse (or *S* for shear) wave, and *P*–*S*, *S*–*S*, and *S*–*P* indicate different reflected waves (denoted by the second letter) produced by the incident wave (denoted by the first letter) at stone/water boundaries. Lines with arrowheads indicate rays along the wavefront propagation direction, and dashed lines are used to show the locations of different wavefronts in water and stone.

LSW–stone interaction and resultant cavitation bubble collapse (see Figure 58.6), the stresses produced inside the stone will be significantly intensified at the tips of the pre-exsiting microcracks, which are the weak spots inside the material (Figure 58.9a). Consequently, if the stress concentration exceeds a threshold value, measured by the fracture toughness of the stone material [38], there will be a progressive opening and growth of the microcracks. They coalesce to form macrocracks (Figure 58.9b), which eventually leads to fracture under repeated LSW bombardments (Figure 58.9c). This dynamic fatigue process is the fundamental mechanism by which stone fragmentation is produced in SWL [14, 39]. Although the theoretical framework has been well described, significant challenges remain in applying the principle of dynamic fatigue to analyze stone comminution because of the lack of understanding about the specific mechanisms that drive fracture formation in kidney stones during SWL [40, 41].

## Traditional theories of stone fragmentation

Extensive research has been devoted to uncover the mechanisms of stone fragmentation in SWL since the invention of this remarkable technology in the early 1980s. Figure 58.10 shows chronologically the primary mechanisms described previously in the literature, including (i) stress gradient and tensile failure at stone/fluid boundaries [42, 43], (ii) cavitation [44–46], (iii) spalling [34, 47, 48], (iv) dynamic fatigue [14, 39], (v) quasi-static squeezing [49], and (vi) dynamic squeezing [41]. Several of these mechanisms, however, are either descriptive or based on stone fracture observed in the early stage of SWL under special circumstances. For example, spalling damage is often produced in large stones with flat surfaces such as a slab (or in lithotripters with a narrow focal width) at the beginning of SWL when the reflected tensile wave from the leading compressive component is superimposed constructively with the trailing tensile component of an advancing refracted P wave (see Figure 58.7a). Spalling will gradually become less effective as the size of fragments decreases [34] or in stones with curved boundaries [40] or when wave attenuation in the stone material is high [50]. As illustrated in Figure 58.8, the intensity of the P wave will decrease when the incident LSW impinges on a flat stone surface from an oblique angle (Figure 58.7b) or a stone with curved boundaries (Figure 58.7c). Moreover, although the importance of shear waves in stone comminution has been recognized for years [34, 40, 41, 49], the mechanism of shear wave generation was not adequently clarifed. In particular, “dynamic squeezing” has often been described in the literature as the dominant mechanism to create strong shear in stones [3, 41] using an idealized stone geometry (i.e., a cylindrical stone placed on the axis of the lithotripter with its flat surface facing the incident LSW). In contrast, as shown in Figure 58.8, the strong shear waves in kidney stones with smooth or curved surfaces are generated by the mode conversion at the proximal surface of the stone produced by the oblique incidence of the LSW based on the acoustical principles described in Box 58.3.

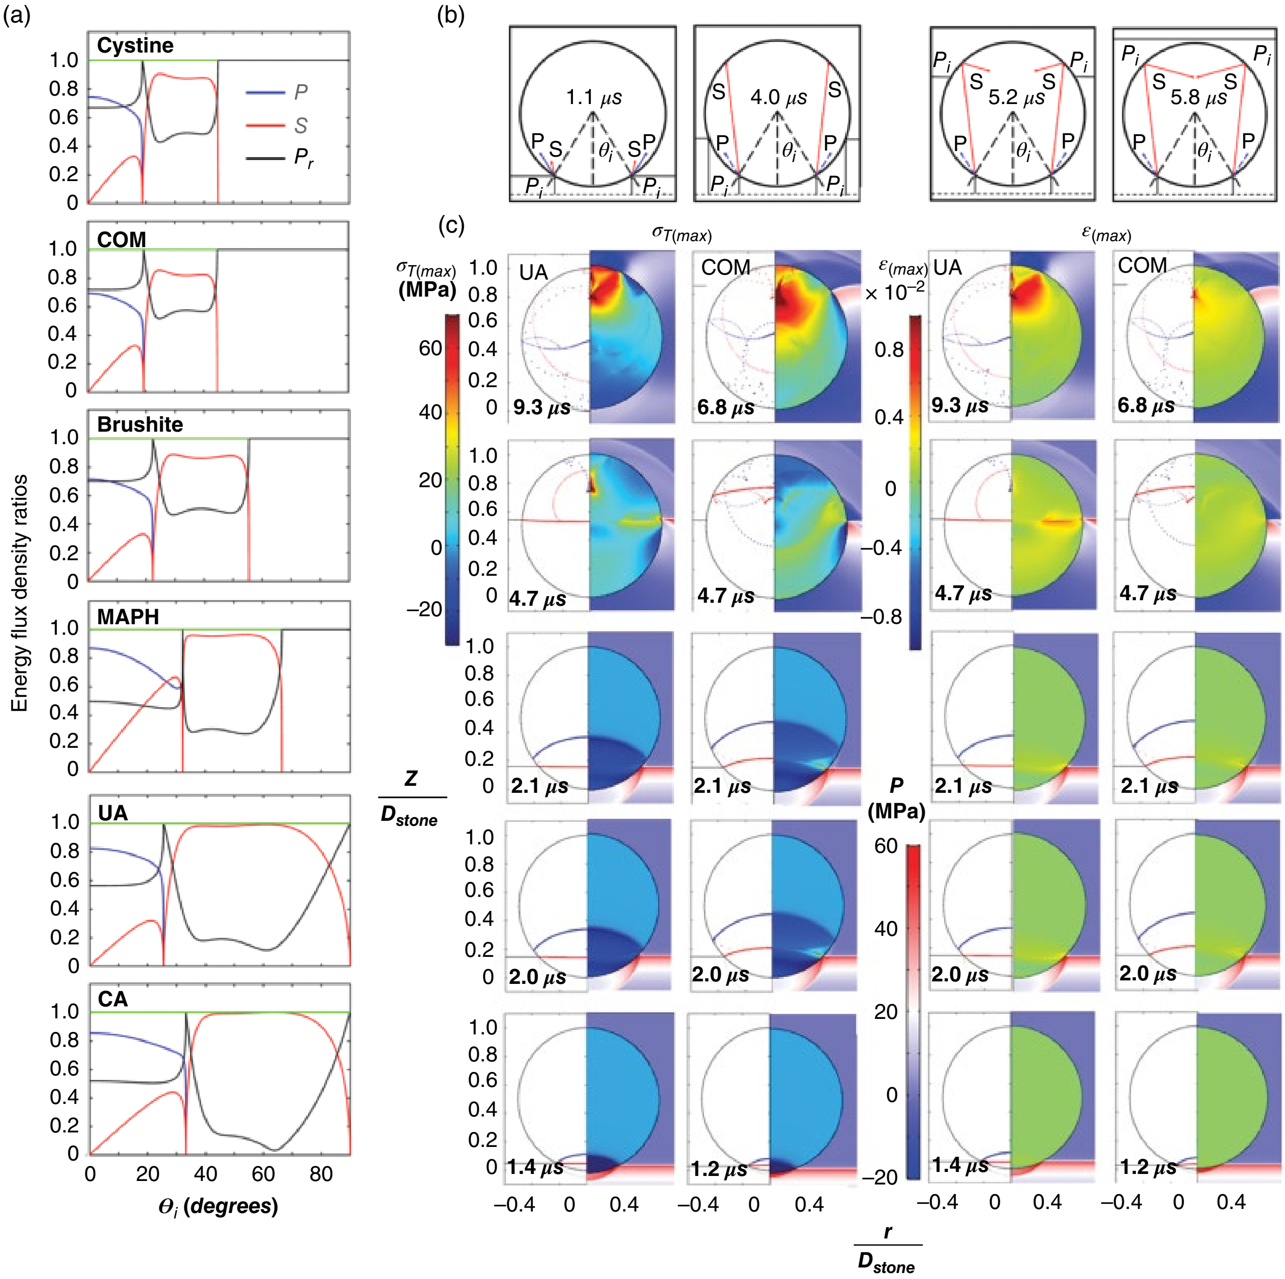

**Figure 58.8** (a) Variations in wave reflection and refraction (transmission) coefficients with incident angle ($\theta_i$) for kidney stones of different compositions; (b) ray tracing showing the generation of P and S waves, and propagation and focusing of *S* wave in a spherical stone; and (c) transient LSW–stone interaction, generation of different stress waves, and the production of maximum tensile stress ($\sigma_{T(max)}$) and maximum tensile strain ($\varepsilon_{T(max)}$) inside COM and UA stones of spherical geometry. ## Contemporary theories of stone fragmentation

While the traditional theories of stone fragmentation often focus on mechanims responsible for creating the initial fracture, contemporary theories of stone fragmentation [15, 51] aim at identifying the key lithotripter field parameters and their interactions that govern the overall process of stone comminution to achieve the ultimate goal of SWL. Based on dimensional analysis (a tool used by engineers to identify the key nondimensional [or unitless] parameter of a particular problem, such as the Mach number for describing the compressibility of a fluid), recent studies have demonstrated a clear correlation between stone comminution and the average peak positive pressure ($P_{+(avg)}$), or the local peak positive pressure of the LSW, incident on the stone

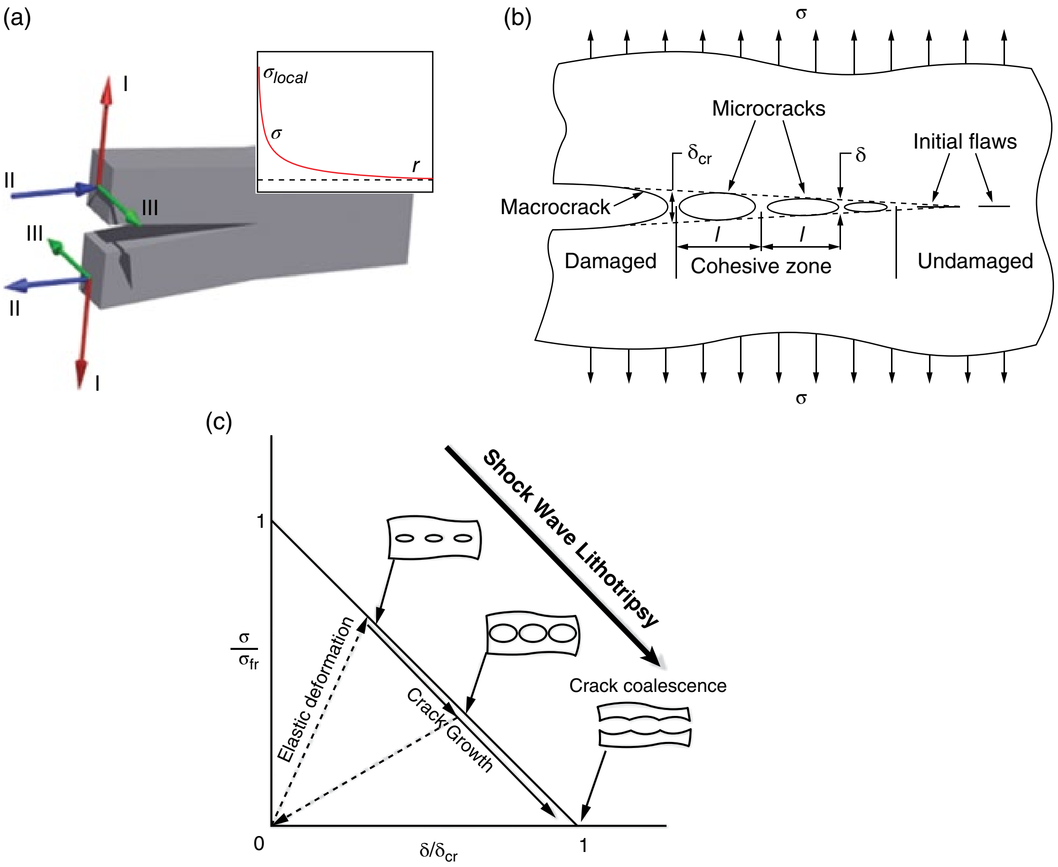

**Figure 58.9** Fundamental fracture mechanics. (a) Stress concentration near a crack tip and three primary modes of brittle fracture: mode I, opening mode due to tensile stress applied normal to the plane of the crack; mode II, sliding mode due to shear stress acting parallel to the plane of the crack and perpendicular to the crack front; and mode III, tearing mode due to shear stress acting parallel to the plane of the crack and parallel to the crack front. (b) Cohesive zone model of dynamic fatigue failure of brittle materials. (c) Progressive microcrack opening, growth, and coalescence in kidney stones during SWL. surface [51]. As shown in Figure 58.11a, this correlation holds true for both hard and soft artificial BegoStone of different geometries and sizes, which cover the broad range of acoustic and mechanical properties measured from kidney stones. More importantly, the results show that there is a distinct threshold of $P_{+(avg)}$ (denoted by $P_f$) for each stone type to initiate fragmentation, independent of the fluid medium around the stone. Hard BegoStone has a higher $P_f$ than soft BegoStone, indicating that material properties of the stone such as the shear modulus ($G$) or Young's modulus ($E$) may also be important in determining the fragmentation outcome. In fact, a new nondimensional parameter, $Z = \frac{P_{+(avg)} - P_f}{G}$, in which $G$ can be replaced by $E$ or $K$ (bulk modulus), has been constructed that unifies all the fragmentation results from both the hard and soft BegoStone samples treated in water [15]. Physically, $Z$ indicates that stone fragmentation in SWL is manifested by the competition between $P_{+(avg)}$ that represents the impact load imposed by the LSW on the stone and $G$ (or $E$) that represents the resistance of the stone materials against shear- (or tension-) induced material deformation.

During SWL, kidney stones are fragmented progressively to smaller and smaller pieces (see Figure 58.1a). It has been shown as the stone (or fragment) size decreases, the $P_{+(avg)}$ threshold will increase [36] (see also Figure 58.11b). This observation has been attributed to the destructive wave interference in stones of small sizes, which will reduce the maximum tensile stress or stress integral that can be built up inside the stone to produce fracture (Figure 58.12a). This finding is consistent with the monotonic decrease in the rate of stone comminution after the initial accelerating phase in stone comminution observed during SWL (see Figure 58.1b). Furthermore, shape and orientation can also profoundly influence the location and magnitude of the maximum tensile stress produced in stones of ellipsoidal geometry with equal

volume but different eccentricities (Figure 58.12b). As eccentricity increases, the "hot" spot corresponding to the region of maximum tensile stress will shift from the anterior to posterior surface of the stone with decreased stress magnitude.

In summary, it is worth noting that the size of the fragmentation zone of a lithotripter is determined by $P_f$ (i.e., the dimensions around a lithotripter focus where the local peak positive pressure is equal or above $P_f$). At a given output setting, the fragmentation zone of a lithotripter will vary for different types of kidney stones (because of their varying elastic stiffness), and will be affected by stone geometry and size (because of their influence on internal wave focusing and interference). In general, the size of the fragmentation zone of a lithotripter will decrease as the treatment progresses unless the output energy is ramped up at the risk of higher propensity for tissue injury.

## Role of cavitation in stone fragmentation

In contrast to stress-wave-induced fracture, cavitation produces primarily surface erosion due to the localized strong secondary shock wave or microjet impact from inertial (symmetric or asymmetric) collapse of bubbles near the stone boundary [52] (see also Figure 58.6). Damage produced by cavitation is largely confined on the surface and does not penetrate deep into the bulk of the stone [53]. Although cavitation activities will intensify as fragmentation progresses [54], it has been shown that stone comminution produced by cavitation alone in SWL is very limited [53]. On the other hand, as shown in Figure 58.11 and other studies, stone comminution produced by stress waves without cavitation will also be significantly reduced [41, 53, 55, 56]. All in all, it has been suggested that both stress waves and cavitation are needed simultaneously in SWL, and they act synergistically to produce effective and successful stone comminution [53].

## A heuristic model of stone comminution in SWL

Recently, a heuristic model that describes the overall progression of stone comminution in SWL has been developed, accounting for the contribution of two important lithotripsy parameters: (i) $P_{+(avg)}$ (controlled by the output kV or energy setting of the lithotripter) and (ii) dose of the shock waves delivered [57]. The model is based on the Weibull theory for brittle fracture [58], incorporating threshold values of $P_{+(avg)}$ and dose that are required to initiate fragmentation. Validated by experimental data obtained both in water and 1,3-butanediol (a viscous medium that suppresses cavitation, but with similar acoustic impedance to water so that LSW transmission and generation of stress waves in the stone are not affected), the model provides physical insight that may directly benefit the design and implementation of safe and effective treatment protocols in SWL. For example, the asymptotic lines in the contour plot of stone comminution in Figure 58.13 suggests that effective treatment can be achieved by using moderate $P_{+(avg)}$ in the range of 15–20 MPa within 2000 shocks. Increasing $P_{+(avg)}$ beyond 20 MPa would not necessarily accelerate stone fragmentation, but may increase the propensity for tissue injury. Similarly, the model also indicates that in the low $P_{+(avg)}$ range of 10–15 MPa prolonged treatment to high doses will only marginally improve stone comminution, at the cost of longer treatment time and, potentially, elevating the risk of tissue injury. The optimal treatment strategy appears to be a progressive ramping of the lithotripter output (and thus $P_{+(avg)}$) that can achieve effective stone comminution with minimal risk of tissue injury, as illustrated by the dashed line in Figure 58.13.

## A unified theory of stone comminution in SWL

Figure 58.14 summarizes the mechanisms and processes of stone comminution in SWL. At the beginning (within a few hundred shocks), multiple mechanisms can be effective in producing fracture because the initial large size and smooth geometry of the stone favor wave focusing and constructive interference of different stress waves produced inside the stone by LSW–stone interaction. Moreover, the pre-existing (or intrinsic) flaws in the stone provide ample weak spots to intensify tensile stress and, as a result, stone fragmentation accelerates. Thereafter, fragments of irregular shapes and smaller sizes are produced, which disrupt the conditions required for internal wave focusing and constructive wave interference. Further, the intrinsic flaw population is gradually depleted, making

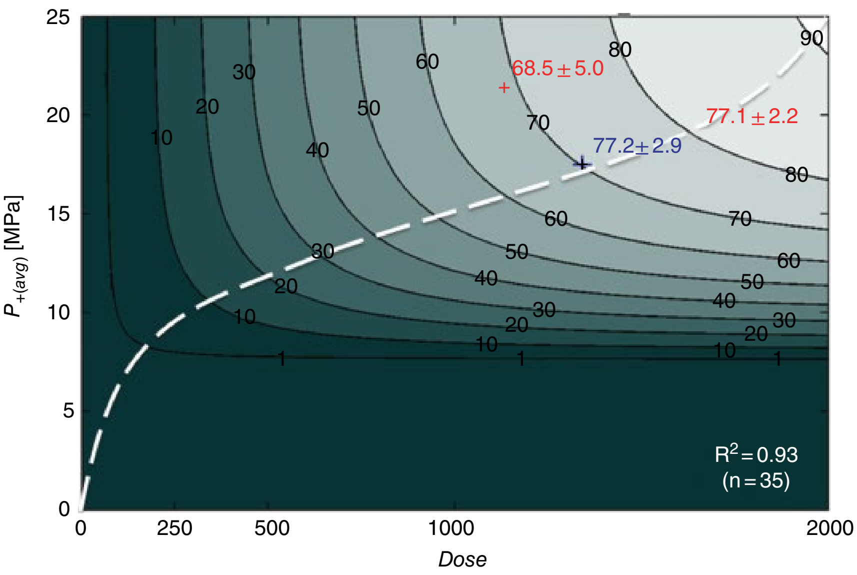

**Figure 58.13** A heuristic model of stone comminution in SWL, adapted from [57]. The contour lines (with numbers) denote the percent of stone comminution as a function of the average positive pressure incident on the stone ($P_{+(avg)}$) and shock-wave number delivered (dose). The dashed line shows an example of the optimal treatment strategy with pressure ramping in SWL. *Source:* from [57] with permission of Acoustic Society of America.

it more difficult to initiate fracture from inside the stone. In addition, after the initial fracture spreading of stone fragments away from the lithotripter focus will effectively reduce the $P_{+(avg)}$ incident on the residual fragment population. Altogether, these multiple factors dictate that stone comminution will decelerate as the treatment progresses. Consequently, in the late stage (if not majority) of SWL, the dominant mechanism of stone comminution is likely to be the $P_{+(avg)}$-driven opening of surface (or extrinsic) flaws produced by cavitation damage, through a synergistic interaction between stress waves (including surface acoustic waves) and cavitation-generating surface pitting [15].

## Tissue injury

There is no doubt that LSWs can cause trauma to renal tissues surrounding the stone, and, in a very few severe cases, even resulted in death of the patient [59–61]. A detailed description of the various clinical complications of SWL is given in Chapter 63 of this book. Here we will focus on reviewing the potential physical mechanisms of shock-wave–tissue interaction that may lead to injury.

As mentioned earlier in this chapter, the cigar-shaped focal region of a lithotripter exceeds the average stone size along the propagation direction of the incident shock waves. Therefore, a significant volume of the kidney, including the perirenal tissues, will be exposed to high-energy and high-pressure shock waves. Moreover, the patient's motion (due to respiration or pain-induced movements) will exacerbate the risk of tissue injury because a significant portion of the shock waves (30–40%) may completely miss the target stone and hit the renal tissue solely [62, 63]. As a result, a higher dosage of shock waves will be needed in a single treatment session, which further increases the risk of renal injury [63].

Tissue injury in SWL has been described mainly as vascular lesions in the form of endothelial cell damage and rupture of small blood vessels along the lithotripter beam path throughout the thickness of the kidney [64, 65]. Based on *in vitro* phantom and *in vivo* animal studies, shear stress [66, 67] and cavitation [68–71] have been hypothesized to be the two main physical mechanisms responsible for tissue injury. Shear stress can be generated by the propagation of LSW through inhomogeneous tissue spaces [14, 39, 67] that may cause injury by accumulated shear deformation, especially in the papilla and at high pulse repetition frequency (PRF) [66]. In addition, LSW-generated rapid and large intraluminal bubble expansion and collapse with resultant significant hoop stress imposed on the vessel wall may cause rupture of capillary and small blood vessels [71, 72]. In contrast, damage in large blood vessels or in the interstitial hemorrhage site may be mediated by LSW–bubble interaction with jet formation [73], a scenario that may be responsible for the deep poration of renal parenchyma produced by narrow focal width and high peak-pressure lithotripters [74]. Furthermore it has been demonstrated that injection of contrast agents for imaging prior to SWL can greatly increase the propensity of renal injury and should be avoided [68, 70].

Although the mechanisms of tissue injury have not been completely understood, several risk factors for tissue injury have been identified, including lithotripter output settings such as PRF, output energy and energy flux density, total number of shocks, and patient characteristics such as pre-existing hypertension in older people, pre-treated kidneys, and pediatric patients [59, 69, 75–77].

Tissue injury in SWL increases substantially at high PRF [69]. Compared to the early days of SWL, it has been advocated in recent years that shock waves should be administered at a slower rate [9]. The benefit has been demonstrated in HM3 that even at the highest output setting of 24 kV tissue injury can be significantly diminished when PRF is reduced from 2.0 to 0.5 Hz [78]. Moreover, current clinical treatment protocols often include an initial priming of the kidney with a low dose of shock waves (i.e., ≈500) at low energy levels followed by a few minutes pausing of the treatment, which has been demonstrated by animal experiments in HM3 to exhibit a protective effect probably due to vasoconstriction [79–81]. However, the mechanism of this tissue-protective strategy is not completely clear and needs to be thoroughly investigated using contemporary lithotripters under clinically relevant output settings.

## New technologies in SWL

### Lithotripters with broad focal width and low peak pressure

Motivated by the success of the self-focusing EM lithotripter (XX-ES) [16], there is a resurgence of new clinical lithotripters (e.g., LG-380 and Lithospace) with broad focal width and low peak pressure, which are the acoustic field characteristics exemplified by the original HM3. Comparison studies between broad focal width (18–20 mm)/low peak pressure (12–30 MPa) lithotripters (LG-380 and XX-ES) and a narrow focal width (≈2.6 mm)/high peak pressure (≈90 MPa) lithotripter (SLX) have shown that the former can disintegrate stones more effectively in a large area around the lithotripter focus [82]. The high peak pressure of the SLX, while beneficial for breaking up stones located precisely at the lithotripter focus, is also responsible for producing more tissue injury [83]. Moreover, the narrow focal width/high peak pressure lithotripter field with its inherently large pressure gradient will exert a strong radiation force on the target stone that may cause more fragment dispersion. In contrast, LG-380 and XX-ES with minimal tissue injury produced even at their maximum output settings are considered relatively safe lithotripters [82]. The advantages of a broad focal width/low peak pressure lithotripter in stone fragmentation have also been attributed to other factors, including (i) a more uniform cavitation field, (ii) progressive fragmentation of the stone, (iii) less dispersion of residual fragments, and (iv) higher $P_{+(avg)}$ or local positive pressure at off-axis locations in the lithotripter field [51, 52, 57, 84]. Overall, a lithotripter with broad focal width and low peak pressure will be more effective for treating stones that are less accurately aligned with the lithotripter focus, or when residual fragments are dispersed or significantly translated away from the lithotripter focus due to respiratory motion of the patient [84].

### New acoustic lens design for electromagnetic shock-wave lithotripters

Over the past two decades, EM shock-wave lithotripters have become the technology of choice primarily due to the durability and reproducibility in output pressure and acoustic pulse energy [85]. However, compared to the gold standard HM3, several fundamental drawbacks exist in EM lithotripters: including (i) the relatively narrow focal width, (ii) the non-idealized pressure waveform exemplified by the secondary compressive wave immediately following the tensile wave, and (iii) the significant shift in the locations of $p+$ (i.e., acoustic focus) and peak negative pressure ($p-$) towards the shock source, especially at high output settings [86, 87].

These fundamental drawbacks have been recently addressed through acoustic lens modification of the Modularis lithotripter. By introducing a groove in the outer region of the original lens (Figure 58.15), the second compressive wave can be eliminated while the focal width of the lithotripter is broadened simultaneously via *in situ* pulse superposition [86]. Under the same effective acoustic pulse energy, the new lens design leads to a lower $p+$ on the lithotripter axis, but higher off-axis local peak pressure

with stronger cavitation activity [87]. Moreover, by reshaping the lens geometry the location of the acoustical focus at high energy settings can be aligned closely with the geometric focus of the lithotripter where kidney stones are placed during treatment. Both *in vitro* and *in vivo* studies have demonstrated that the new lens can significantly improve stone comminution with minimal tissue injury under clinically relevant energy settings [87]. Because of the simplicity in the modification, this design upgrade of acoustic lens or reflector can be easily implemented in principle in all clinical EM shock-wave lithotripters.

## Other emerging technologies and techniques in SWL

There are other emerging technologies under investigation that require substantial modifications of the lithotripter system. For example, tandem pulse technology has been extensively evaluated in a hybrid EH-PE shock source with coaxial alignment [88, 89], dual shock-head source aligned either opposite to each other [90], or at an acute angle [91], and a single PE source driven by a dual high-voltage pulse generator [92], all aimed at promoting the contribution of cavitation in stone comminution. Despite proof of principle, challenges exist in the cost-effective integration of the tandem pulse technology in clinical lithotripters and evaluation of its impact on tissue injury.

Treatment monitoring is another area with active research, including stone targeting via spectral Doppler ultrasound [93] and assessment of stone fragmentation via cavitation-produced acoustic emission [94] or acoustic scattering from residual fragments [95]. In most cases, further refinements are needed before clinical applications. It should be noted that there is no current imaging technology that can monitor tissue injury during SWL.

More recently, transcutaneous pulsed focused ultrasound has been demonstrated to displace stones or fragments in the renal collecting system without thermal damage [96]. This technology may be used to facilitate stone clearance following successful SWL. Focused ultrasound has also been used in burst wave lithotripsy to effectively fragment artificial and natural stones fixed on a holder *in vitro* using focal pressure of 6.5 MPa at less than 200 Hz burst repetition rate [97]. Further studies under clinically relevant conditions and *in vivo* experiments to assess potential tissue effects are warranted [97]. Finally, several techniques of cavitation manipulation have been demonstrated *in vitro* for either removing residual bubbles in the coupling medium using a turbulent jetting flow [98] or along the lithotripter beam path [99, 100] and near the stone surface using low-pressure ultrasound bursts [101] for improved treatment efficiency.

## Summary

As a remarkable engineering innovation, SWL truly represents a milestone in the surgical management of urolithiasis. Because of its non-invasiveness and easy of use, SWL still remains as the therapy of choice for a majority of patients with kidney and upper urinary stones. In parallel to the widespread clinical applications, our understanding about the general physical principles

**Box 58.4 Future outlook.**

- Development and integration of novel SWL technologies into contemporary clinical shock-wave lithotripters, including the design of new shock source and focusing device, miniature wet coupling technique, adaptable and steerable beam formation in lithotripter fields, cavitation control and monitoring.
- Development of real time (acoustic) tracking of the stone or large residual fragments to fire shock waves only if the stone is in the focal zone. Development of acoustic techniques to monitor stone comminution process so that the treament can be stopped once the stone is sufficiently fragmented.
- Development of new imaging techniques for real-time monitoring of hemorrhage and hemotama formation in peri- and intra-renal tissues, which will be crucial and necessary for establishing a pressure or energy flux density based threshold for tissue injury in SWL. With this knowledge, we'll be able to better define the lithotripter output parameter space to ensure a safe and effective treatment using high-energy shock waves.
- Development of pulsed focused ultrasound techniques for effective and safe fragmentation of kidney stones with reduced treatment time or clearance of residual fragments from the collecting system following successful SWL.
- Further improvement in the fundamental understanding about the physics of SWL and the mechanisms of stone comminution and tissue injury will help us in rational selection of lithotripter characteristics and output settings to optimize treatment strategy for maximal stone fragmentation with minimal tissue injury and adverse effects.

and process of SWL has improved significantly in the past two decades. The state-of-the-art theories regarding stone fragmentation and tissue injury during SWL are reviewed in this chapter. In the following, we summarize several main points pertinent to current status of SWL together with future overlook outlined in Box 58.4:

- EM and EH technologies for shock-wave generation and associated focusing means are predominantly used in contemporary clinical lithotripters while PE technology is less favored because of limited acoustic energy output. There is a trend of resurgence in broad focal width and low peak pressure lithotripters, exemplified by the original HM3.
- Dry coupling has replaced wet coupling in almost all contemporary lithotripters in favor of user convenience, but at the cost of providing an imperfect coupling interface between the shock source and the patient. Problems may arise in shock-wave transmission if care is not taken in ensuring the quality of the coupling interface.
- The acoustic field of a lithotripter is determined primarily by the design characteristics of the shock source and focusing device. Among clinical lithotripters, the maximum of peak positive pressure of LSWs varies in the range of 20–120 MPa, with the minimum of peak negative pressure in the range of –4 to –12 MPa. The focal width of clinical lithotripters varies from 2 to 20 mm, and is inversely correlated with the aperture angle of the shock source.
- Stone fragmentation in SWL is the consequence of dynamic fatigue produced by stress waves and cavitation generated by lithotripter shock-wave–stone interaction. Stress waves (longitudinal, transverse, and surface acoustic waves) and associated tensile and shear stresses are the primary driving forces to create fracture, initially from the pre-existing (or intrinsic) flaws or weak spots in kidney stones. In contrast, cavitation produces pitting and therefore introducing new weak spots (or extrinsic flaws) on the stone surface, leading to weakened mechanical integrity of the stone. Caviation induced in SWL is not sufficiently strong enough to disintegrate stones. Stress waves and cavitation are both necessary and work synergistically to produce effective and successful stone comminution in SWL. Cavitation damage can be considered as catalysts to enhance the efficiency of stress-wave-driven stone fracture.
- Average peak positive pressure incident on a stone, $P_{+(avg)}$, has been identified as a key lithotripter field parameter that is directly correlated with stone comminution. The threshold of $P_{+(avg)}$ to initiate stone fracture depends on the composition, geometry, and size of the stone. Kidney stones with higher wave speeds, acoustic impedance, and fracture toughness, such as calcium oxalate, brushite, and cystine stones, are more difficult to disintegrate than those with lower corresponding values such as uric acid, carbonate apetite, and struvite stones. A new nondimensional parameter $Z$ has been identified that can be used to gauge the effectiveness of lithotripter field in stone comminution.
- Tissue injury in SWL is related to shear stress and cavitation, yet the exact mechanism has not been completely determined. In SWL, it is crucial to ensure treatment safety before pursuing treatment efficiency. Lowering peak pressure, energy flux density, PRF, and

dose of shock waves delivered in a single treatment have all been demonstrated to lessen the risk of tissue injury during SWL.

- A heuristic model accounting for the effects of both $P_{+(avg)}$ and dose has been developed to assess the overall process of stone comminution in SWL. The model suggests that a progressive ramping of the lithotripter output (and hence $P_{+(avg)}$) will be effective for achieving successful stone comminution with minimal risk of tissue injury.
- New technologies in SWL, such as self-focused EM shock-wave lithotripter and the new acoustic lens for Modularis or other EM shock-wave lithotripters, have been either developed or demonstrated. Other promising technologies and techniques for improving treatment efficacy and safety will continue to emerge. The integration of new technologies into clinical lithotripters will depend critically on the demand by urologists for better and safer lithotripters as well as the desire of medical device manufactuers to bring them to the markert to alleviate millions of kidney stone patients worldwide from their painful conditions.

## Acknowledgments

We would like to thank Dr Glenn Preminger and Dr Michael Lipkin for their long-term collaborations and support of our research in SWL, and Ying Zhang for producing several figures used in this chapter. This work was supported in part by Ferdinand Eisenberger Grant NeA1/FE-11 from the Deutsche Gesellschaft für Urologie (A.N.) and by a NIH grant 4R37DK052985 (P.Z.).

# Lithotripsy Systems

*Geert G. Tailly*

*Department of Urology and Pediatric Urology, AZ Klina, Kapellen, Belgium*

## Historic perspective

Prior to the introduction of extracorporeal shock-wave lithotripsy (ESWL) and other minimally invasive techniques such as percutaneous nephrolithotomy and ureterorenoscopy, open surgery was the principal treatment modality for urolithiasis. The first extracorporeal shock-wave lithotripsy (ESWL) that was performed on a stone-bearing patient in 1980 therefore thoroughly revolutionized modern stone management. As early as 1963 physicists at Dornier, an aircraft manufacturer in Friedrichshafen, Germany, had investigated the impact of raindrops on flying objects, as these impacts caused shock waves which not only damaged the outer shell of airplanes but also structures within. During these experiments an engineer at Dornier accidentally discovered the effects of these shock waves on biological tissue. At the same time the German Ministry of Defense was also interested in the interaction between shock waves and biological tissue. In 1974 a partnership to conduct research on the application of shock waves in humans was formed between Dornier Development and Research (W. Hepp and G. Hoff), the Department of Urology at the Ludwig-Maximilians Universität in Munich (E. Schmiedt and F. Eisenberger), and the Institute of Surgical Research at the same university (W. Brendel and Ch. Chaussy). Funding was obtained through the German Research and Technology Ministry [1–3].

Early on it was found that shock waves caused no damage when traveling through muscle, fat, or connective tissue, except at transition zones with high acoustic impedance. In the course of this project someone then formed the idea to fragment kidney stones in the human body [1, 2]. After extensive experiments the first lithotriptor for human treatment, the Dornier Human Model 1 or HM1, was built, in 1979.

Patient selection for the first treatments was very strict:

- a radiopaque stone not larger than a cherry pip in the renal pelvis
- unobstructed urological tract
- no urinary tract infection
- no comorbidities.

The first patient was successfully treated using a Dornier HM1 on 7 February 1980 by Christian Chaussy, B. Forssmann, and D. Jocham [4]. The results of the first clinical study on 221 treatments in 206 patients were published in 1982 [5]. In order to promote the new technique as reproducible and safe, the HM1 needed several improvements:

- an improved X-ray system
- an improved patient support
- an improved installation to produce the 1200 liters of degassed water for the waterbath
- an improved shock-wave generator
- an ellipsoid with a treatment depth of 13 cm.

The Dornier HM3 was born.

In 1983 the second lithotripsy center was opened in the Department of Urology (F. Eisenberger) of the Katharinen Hospital in Stuttgart. In March 1984 the first Dornier HM3 in the United States was installed in the Methodist Hospital in Indianapolis (Daniel M. Newman and James E. Lingeman). A study for marketing approval by the US Food and Drug Administration was monitored by Georges Drach [6]. The rest is history.

Originally lithotripters were devices only dedicated to shock-wave lithotripsy (SWL). With modern stone management demanding a judicious combination of endourologic techniques and SWL, there was an evolution toward the construction of multifunctional urologic

Companion website: www.wiley.com/go/smith/textbookofendourology

workstations. A modern stone center needs to tailor the most appropriate treatment to both the patient and their stone. A multifunctional workstation where both endourological techniques and ESWL can be performed in great comfort therefore seems an essential tool.

## Components of a lithotripter

The Dornier HM3 lithotripter represented the archetype of the first-generation lithotripter, characterized by a large water bath in which the patient was immersed for optimal shock-wave coupling. Equipped with an electrohydraulic shock-wave source and an ellipsoidal reflector with a small aperture to focus the shock wave, the treatment required general or spinal anesthesia. A bidirectional fluoroscopic imaging system allowed targeting to move the stone into the therapeutic focus F2. Multifunctional or multidisciplinary use was impossible. The results achieved with this device are still considered the basis for comparison in evaluating all new devices.

Second-generation lithotripters utilize an electrohydraulic, electromagnetic, or piezoelectric shock-wave source. Transmission of the shock wave is provided by means of a water cushion or partial water bath. Stone localization is performed with an ultrasonic or fluoroscopic imaging system [7–10]. The anesthesia requirements have been reduced so that SWL can be performed without any medication or only in analgosedation. Multifunctional or multidisciplinary use is limited.

Third-generation lithotripters are also equipped with an electrohydraulic, electromagnetic, or piezoelectric shock-wave source. All systems allow anesthesia-free treatments. Apart from that they use both fluoroscopy and ultrasound, alternately or simultaneously, to target the stones. Finally, all components are integrated into a multifunctional system with a treatment table allowing both SWL and endourologic procedures to be performed on the same device.

### Shock-wave sources

Shock waves are acoustic waves. Acoustic waves are mechanical waves consisting of pressure and density variations which can travel through media in any of its phases: gaseous, liquid, or solid. They are also referred to as pressure waves. Acoustic waves propagate through a medium by alternating decompression and compression of the medium. At the interfaces of the media they pass, absorption, reflection, or refraction of the shock waves can occur [11]. An acoustic wave of very short duration is called an acoustic pulse and a shock wave is a very short acoustic pulse. On the wave front the positive pressure rises in a very short time from the ambient pressure to the maximum pressure. Afterwards a short phase of underpressure follows. While the wave propagates through the medium, it gets continuously steeper until it forms a shock wave. The generated shock wave is characterized by a sudden drop from overpressure to underpressure. The short phase of underpressure generates cavitation in the transmission medium. The bubbles induced by cavitation subsequently collapse violently and create microjets or secondary shock waves. For medical purposes shock waves are generated in water and transmitted into the patient's body using a (partial) water bath or a water cushion for coupling. Water is used as transmission medium due to having comparable acoustical properties to human tissue, leading to impedance matching with low reflection at the contact surface between the water bath or water cushion and the patient.

In the Dornier HM3, the first lithotripter commercially available, shock waves were generated using an electrohydraulic shock-wave source. In second- and third-generation lithotripters any of three principles of shock-wave generation are used: electrohydraulic, electromagnetic, or piezoelectric.

#### Electrohydraulic shock-wave sources

#### *Electrohydraulic shock-wave generation*

Electrohydraulic shock-wave generation is based on an underwater spark discharge. A spark plug with two opposing electrode tips is positioned in the focus F1 of an ellipsoidal reflector. A capacitor of about 100 nF connected to the spark gap is charged to a voltage of 15–30 kV and then abruptly discharged, producing a fast-growing plasma channel between the electrode tips and resulting in rapid vaporization of the surrounding water like a micro-explosion. This releases a spherical shock wave that is reflected by the wall of the ellipsoidal reflector towards the therapeutic focus F2 of the reflector. The intensity of the shock wave can be adjusted by changing the discharge voltage. The treatment depth and focusing are defined by the geometrical parameters of the ellipsoidal reflector. This type of shock wave is still used in lithotripters today, and the shock-wave source of the HM3 is still considered to be the most effective of this type. Electrohydraulic shock waves have the disadvantage, in that the life span of the electrode tips is limited to several thousand shocks. Degradation of the electrode tips causes output variations and instabilities of the focus position, particularly near the end of the electrode's lifetime.

#### *Electroconductive shock-wave generation*

To compensate for the degradation of the electrode tips which causes variations and instabilities of the focal position and energy and limits the life span of the electrode to several thousand shocks, Technomed developed a modified electrohydraulic generator, the Diatron IV, an electroconductive shock-wave generator.

The electroconductive generator is a 100 nF generator connected to an electrode immersed in a highly conductive solution instead of degassed water. Due to a better conduction of electricity this highly conductive solution allows an extremely accurate spark position. This combined with reduced interelectrode distance leads to a reproducible and consistent focal spot. This spark gap technology also allows the generation of a focal zone that varies in size with the power output.

An automatic pressure regulator permanently adapts the voltage input to consistently deliver the requested pressure to compensate the variations due to electrode wear and also controls the total energy delivered to the patient.

### Electromagnetic shock-wave sources

#### *"Flat coil" electromagnetic shock-wave emitter*

The electromagnetic shock-wave emitter (EMSE; Dornier, Siemens) features a flat coil that generates a strong magnetic field when a high current pulse flows through it. This field causes an isolated metallic membrane to be repelled into the surrounding water. This causes the water in the vicinity of the membrane to be compressed and a plane acoustic pulse is released, which is focused into the therapeutic focal area by a lens. The pressure across the membrane surface is essentially constant. During propagation to the focal area the pressure pulse undergoes nonlinear effects, leading to the generation of a shock wave. Specifically, the pulse's rising slope becomes steeper and the pulse duration becomes shorter. Since the electromagnetic shock-wave generation principle does not rely on the dielectric breakdown of a liquid, all the associated threshold effects and arc-forming instabilities are avoided. An EMSE can therefore produce effective pressure pulses over a very wide intensity range with a high degree of reproducibility. This wide dynamic range allows for different shock-wave treatment strategies to be used. The instrument's life time is in the order of 1 million pulses. An EMSE does not show progressive degradation in its output power but it needs to be exchanged on a regular basis when the insulating materials and the metals have reached their endurance limits.

The plane acoustical pulse generated by the EMSE is focused by an acoustic lens. The choice of the diameter of the EMSE and the focal length of the lens define the aperture angle of the system. The wide dynamic range that is available for EMSE systems, together with the wide choice of aperture angles, provides a unique toolbox for the designer, serving the different needs of shock-wave field shaping in lithrotripsy, in orthopaedic shock-wave application, and in other emerging applications. An EMSE is easily incorporated into a multifunctional device. Newer EMSE designs provide treatment results comparable to or even better than the results with the unmodified Dornier HM3.

There is ongoing research to improve the performance of electromagnetic lithotripters through modification of the lens geometry [12].

#### *Storz electromagnetic shock-wave source: cylinder source with parabolic reflector*

The electromagnetic cylinder source was also developed to overcome some drawbacks of the powerful but unstable spark gap technology with a short life span of the eroding electrodes. The cylinder generator is based on a hollow electromagnetic cylinder composed of a cylindrical coil covered by an insulating membrane, which again is covered by an electrically conducting membrane of high strength. An intense pulse current with short rise time generates repelling pulse forces due to electromagnetic induction. When immersed in water the radially expanding membrane generates, primarily, an acoustic cylinder wave which is focused by a special rotational parabolic reflector. The principle works on the same basis as a loudspeaker, but with very intense and short acoustic pulses.

The cylindrical coil/membrane configuration is very stable and delivers more than 1 million pulses without degradation or significant fluctuations of acoustic energy. The parabolic reflector can be designed with large apertures and, accordingly, large aperture angles without technical limitations. Due to the large aperture angle, the acoustic energy can be concentrated to laterally narrow and axially short focal zones with high peak pressure and high energy flux density values. Thus, the fragmentational shock-wave energy is restricted to a relatively small area, reducing tissue lesions in front or behind the target stone. Also, anesthesia requirements and shock-wave load affecting the coupling area at skin level are minimized. Contrary to the electrohydraulic spark gap technology, the energy level of each single shock-wave pulse can be precisely adjusted between very low (painless) and powerful settings, exactly matching the pain tolerance of the patient.

The generator configuration featuring a hollow cylinder provides sufficient space for favourable inline localizations either for fluoroscopic or ultrasonic targeting [13–15].

### Piezoelectric shock-wave sources

Piezoelectric shock-wave generation was developed simultaneously by EDAP and Wolf [16–20]. The conversion of electrical to acoustic energy takes place in ceramic platelets that expand or contract in the surrounding water because of the piezoelectric effect when a pulse of several thousand volts is applied. Several dozen to several thousand platelets are usually mounted on a spherical segment transmitting the shock wave into the center of the sphere through direct focusing. However, compared to other generation principles the intensity of a typical piezoelectric generator is lower and a large converter surface is required to mount the platelets. The diameter of such a shock-wave source is therefore large, providing sharp focusing of the acoustic pulse. The large diameter of the piezoelectric dish makes its incorporation in a multifunctional device more problematic, however. The piezoelectric shock-wave source of the Wolf Piezolith 3000 features a double layer of piezo-ceramic elements, known as Double Layer Piezo-technology.

Each type of shock-wave source produces a shock wave, i.e. an acoustic pulse of which the energy is focused towards and concentrated in the therapeutic focus. In an electrohydraulic lithoptripter the focusing is achieved by a semi-ellipsoid reflector, whereas in an electromagnetic lithotripter shock waves are focused using an acoustic lens (Dornier, Siemens) or a parabolic reflector (Storz). In a piezoelectric system there is no focusing as such. Each ceramic crystal is to be considered as a separate point source that produces its own miniature shock wave. The ceramic crystals are arranged on a dish that directs the point sources towards the therapeutic focus, where the accumulation of the energy of all these separate point sources produces sufficient energy for stone fragmentation: direct-focusing lithotripsy (DFL).

#### Burst-wave lithotripsy

In a recently published experimental *in vitro* study bursts of high-intensity ultrasound are used to disintegrate artificial and real urinary calculi. The conclusion of the *in vitro* study was that *in vitro* burst-wave lithotripsy is feasible. The clinical use of this novel and interesting technique will of course depend on *in vivo* clinical studies proving both efficiency and the exclusion of adverse tissue effects [21, 22].

## Introduction to shock-wave physics

A shock wave is an acoustic pulse characterized by a very fast rise time, a very high overpressure, a very short pulse duration, and a phase of underpressure. The physics of shock waves being very complex [11], a basic understanding of some of the parameters in shock-wave physics is useful (see also Chapter 58 in this volume). Only the more clinically relevant parameters will be discussed here.

### Maximum treatment depth or penetration depth

The maximum treatment depth is the distance between the shock-wave head and the point of highest pressure in front of the shock-wave head. This is the geometrical focus. The shock-wave focus, however, is cigar shaped, with the axial dimension longer than the lateral. This means that there is still energy that may be sufficient to break a stone beyond the geometrical focus. This is referred to as the “blast path.”

In their published specifications some manufacturers may “extend’ their treatment depth by also incorporate the blast path, thus adding half of the focal length to the geometrical focus and “stealing” some distance.

### Clinical relevance of focus size

There is an ongoing debate on the ideal focus size in a lithotripter [21, 22]. The ideal focus would be a spherical volume exactly matching the size of the targeted stone, thus limiting the administration of energy to the stone and avoiding hitting the surrounding tissue, which would lead to adverse tissue effects [21, 22]. This is technically not feasible, however. Today’s lithotripters have a cigar-shaped focus with energy delivered in front, behind (blast path), and adjacent to the target.

A small focus is highly confined and sharp. The higher pressure in a small focus leads to high efficiency in fragmenting hard stones. In order to obtain optimal fragmentation and to avoid adverse tissue effects, precise targeting is essential. In a large focus pressure is lower. Precise targeting is less critical but there is an increased analgesia need and a higher risk of adverse tissue effects.

Sometimes there is a demand for larger focal zones in order to treat larger target volumes even if surrounding tissue may be affected more than technically necessary. To respond to this demand Storz introduced dual-focus technology. The design of the electromagnetic cylinder source offers the possibility to select different focal zones, precise and extended, according to clinical and anatomical conditions. By modification of the electrical excitation of the coil, longer pulses may be genereated which, in turn, stretch the focal zone, both laterally and axially.

The Wolf Piezolith 3000 features a triple focus: F1, small focus with high energy density (ED); F2, intermediate focus with medium to high ED; F3, larger focus with medium ED. Prospective trials would be useful to document the clinical benefits of selectable foci.

### Shock-wave interaction mechanisms

It is generally assumed that a combination of four different mechanisms is involved in the interaction between shock waves and the targeted stone: the Hopkinson effect, cavitation, quasistatic squeezing, and dynamic fatigue [7]. It is also assumed that cavitation and shear forces (the Hopkinson effect) are the main culprits in the origin of adverse tissue effects. Although both shear forces and cavitation are important and necessary in the stone comminution process, avoidance of the negative effects of shear forces and cavitation is considered important in reducing adverse effects due to shock waves.

The idea behind the dual-pulse technique [23, 24] is to "fill" the negative part of the pressure pulse with a positive pressure pulse. In the Direx Duet dual shock-wave sources are used. Fired synchronized or asynchronized they allow an increase in the total pressure and the shock-wave rate. Sheir et al. [23] demonstrated improved stone comminution with a synchronous discharge of a twin pulse. In another study [24] the same group demonstrated higher performance and efficacy with this twin-head, twin-pulse technique. At the same time this technique produced far less parenchymal damage than with the use of a single treatment head. Theoretically this would reduce cavitation and improve disintegration.

In ongoing efforts to engineer better lithotripters several studies have been and are being conducted to control cavitation and reduce its adverse tissue [25–28]. Eisenmenger and colleagues [29–31] advocate the use of a wide focus with lower pressure to enhance quasistatic squeezing, as this would presumably reduce tissue trauma and improve disintegration. This low-pressure, wide-focus technology is incorporated in the electrohydraulic Lithospace from Jena Med Tech GmbH (Jena, Germany) and the electrohydraulic LithoGold LG-380 from MTS (Konstanz, Germany). In a study by Bhojani et al. [32] comparing the electromagnetic Modulith SLX to the LithoGold LG-380 stone-free rates proved modest with both devices using SWL alone. Outcomes with both systems also proved similar. In this study an advantage of the wide-focus, low-pressure principle could not be demonstrated. Further prospective clinical studies to corroborate (or disprove) this concept are eagerly awaited.

## Coupling

Shock waves are acoustic waves that travel through a medium by alternating decompression and compression of the medium. Absorption, reflection, or refraction of the shock waves can occur at interfaces between media with different acoustic impedance. As water has comparable acoustical properties to human tissue, shock waves are generated and transmitted in water. In order to minimize energy loss of the shock wave at the interface between the patient and the shock-wave source, coupling between shock-wave source and patient is extremely important [31].

Total immersion of the patient in a water bath with degassed water where the shock wave is generated (Dornier HM3) is still considered the ideal coupling system. Second- and third-generation lithotripters, however, feature "dry" coupling which consists of a water-filled cushion that is inflated and pressed against the patient. The water cushion is made of elastic PVC or silicone, and is capable of adapting to the body shape of the patient. In order to guarantee good acoustic transmission, the water cushion is coupled to the patient through the application of ultrasound gel as an interface. In this process, both air bubbles in the coupling gel and folds in the water cushion could impair the transmission of acoustic waves. Even tiny air bubbles in this interface can lead to uncontrolled shock-wave attenuation.

In an *in vitro* experiment, Pishchalnikov et al. [33] found a reduction in fragmentation of 20–40% when air bubbles were included that covered an area equal to 2% of the cushion surface. Decoupling the cushion from the test basin and recoupling it led to a drastic increase in air inclusions. This has led to the recommendation that, if one decouples the patient during treatment, one must repeat the coupling procedure, including cleansing the coupling cushion and subsequently reapplying gel. Based on their own stone model, Jain and Shah [34] were able to identify a considerable influence of air inclusions on the erosion capacity of the shock wave.

After experimenting with various techniques for gel application, as a method of choice Neucks et al. [35] recommend applying the gel as a bolus, specifically from a vessel with a large opening. A small vessel opening and manual distribution of the gel lead to increased air pockets and poor disintegration results. Bergsdorf et al. [36] also recommend the selection of a proper coupling gel disc or gel with low viscosity and the accurate removal of air bubbles to improve efficiency in SWL.

In an experiment with an electromagnetic Dornier lithotripter equipped with an inline ultrasound scanner, Bohris [37] demonstrated that 43% more shock waves were needed to fragment model stones when only 8% of the coupling area, visualized with an inline ultrasound scanner, was covered with air bubbles. Li et al. [38] observed that the coupling interface is invisible during treatment and that the real problem is to avoid the entrapment of air bubbles during the coupling process. To monitor the coupling area in real time during stone treatments Bohris et al. [39] installed a video camera in the therapy head of a Dornier Lithotripter SII. In only 10 of 30 treatments could good coupling with an air ratio of less than 5% be obtained and in eight treatments the air ratio was higher than 20%.

In a prospective clinical study using opical coupling control (see Figure 59.6 below) in a Dornier Gemini Tailly and Tailly-Cusse [40] achieved comparable effectiveness quotients (EQ) with a reduction in shock-wave numbers of 25.4% for renal and 25.5% for ureteral stones leading to a corresponding 25% reduction in treatment time. Energy levels could be reduced with 23.1% for renal and 22.5% for ureteral stones. In this study a video camera incorporated in the therapy head of a Dornier Gemini lithotripter allowed visual monitoring of the coupling area. Air bubbles that inevitably were trapped in this coupling area could easily be removed by gently swiping a hand between the patient and the water cushion, thus consistently achieving perfectly bubble-free coupling.

## Imaging systems

Adequate imaging is vital to the success of ESWL:

- localization and targeting of the stone
- surveillance of treatment progress
- identification of fragmentation.

Imaging modalities available on a lithotripter will to a great extent also define treatment strategies.

Early lithotriptors were equipped either with ultrasound or fluoroscopy. In order to meet all the challenges in modern integrated stone management present day lithotriptors ideally should be equipped with both imaging modalities, to be used either independently and alternately or simultaneously. Inline use of both modalities is essential.

Fluoroscopy allows targeting of radiopaque stones at all levels of the urinary tract. Direct targeting of radiolucent stones is impossible, however. Also smaller renal stones may prove more difficult to locate than with ultrasound. Further drawbacks are the absence of real-time imaging and the exposure to radiation. With ultrasound it is generally impossible to locate stones in most parts of the ureter. On the other hand ultrasound allows direct visualization of radiolucent stones and offers easier targeting of smaller renal stones. A major advantage, however, is the real-time imaging which provides better monitoring of the fragmentation process in the absence of exposure to radiation.

Inline scanners are positioned along the shock-wave propagation path and offer easier targeting of very proximal and very distal ureteral stones and easier dissociation between multiple stones. Image quality usually is poorer than with a lateral outline or free-hand scanner, however, and rib shadows may hide stones from view.

Outline scanners (free-hand or mounted on a lateral isocentric arms) offer far better image quality and allow the selection of the most appropriate window to avoid rib shadows. Usually the appraisal of fragmentation is superior to an inline scanner. Proximal ureteral stones may be more difficult to find and targeting and positioning of prevesical stones is more cumbersome.

To enhance targeting precision several manufacturers offer autopositioning and/or tracking systems: Dornier, EDAP TMS, Jena Med Tech, Storz, and Wolf. Machines where both ultrasound and X-ray are integrated offer the most versatile imaging and targeting possibilities. Ideally these machines offer simultaneous online use of both ultrasound and X-ray. Targeting versatility is further improved by the possibility to couple the therapy head to the patient both under and above the treatment table.

Improved imaging and improved targeting will have a positive effect on the EQ.

## Lithotripter design

### Dedicated or multifunctional machine?

In the years following its introduction ESWL was the privilege of high-volume stone centers. This was mainly due to the high capital, running, and maintenance costs of the first lithotripters. Only “dedicated” to extracorporeal lithotripsy these machines could only be operated in large centers with a high volume of stone patients. The construction of less expensive second- and third-generation lithotripters with lower capital cost and lower running and maintenance costs made extracorporeal lithotripsy available in more and more centers, leading to a reduction of the number of patients treated per stone center.

Stone therapy guidelines from international expert boards consider SWL in most types of stones as the first choice of treatment. However, in some indications endourologic procedures give equivalent or better results than SWL. Modern lithotripters are supposed to support urologists in any of these modalities. Consequently, in the past two decades lithotripters have undergone a transition from pure shock-wave-generating devices to multifunctional urologic workstations.

One of the key components of such urologic workstations is the patient table. An increasing number of obese patients demands high-load-capacity tables with maximum accessibility in order to be able to approach the patient from all sides. For fluoroscopic imaging both in SWL and endourologic procedures the tabletop needs to be radiotransparent. Modern tabletops are therefore made of carbon fiber.

Imaging modalities in a multifunctional workstation need to support the wide range of therapeutic options in urology. Large image intensifiers up to 40 cm ideally offer a large field of view of nearly the entire urinary tract. Full digitization of the X-ray imaging chain provides excellent image quality at low radiation doses. In the newer devices flat-panel detectors (FPDs) replace the traditional image intensifiers. Increasing awareness of radiation safety and dose reduction make ultrasound stone localization an ideal tool for stone targeting and accurate therapy monitoring. Last but not least, a high-performance shock-wave source, which ideally can be coupled to the patient in an over- and undertable position, completes the design of a multifunctional lithotripter.

## Integrated or modular?

Multifunctional machines can have a modular design, where all components are independent and connected according to need, or an integrated design, where all components are integrated in the machine and ideally adapted to their function. A third design, the "hybrid," offers integration of imaging and/or therapy head in a common console with an independent treatment table.

### Modular design

In a lithotripter with a modular design (Figure 59.1) the different components, shock-wave source, imaging components, and treatment table are separate modules to be connected to perform ESWL or endourological procedures. As the imaging components, both a fluoroscopic C-arm and an ultrasound machine are usually available on site; investment cost is thus lower and limited to the shock-wave module. The imaging components can also be used for other purposes both in urology and other departments. Modular systems have no need for a dedicated lithotripsy room and are easily transported from one center to another.

Due to the *ad hoc* combination of different modules the footprint is larger and the floor is cluttered with an array of machinery. In endourologic procedures this footprint is still enlarged by the addition of an electrosurgical unit, light sources, and monitors, etc. The uro-table is less urologist-friendly with limited accessibility. Overall handling is more complicated and less user-friendly.

### Integrated design

In an integrated design the different components are fully integrated in one stand alone system (Figures 59.2–59.4). These systems have a small footprint compared to the modular and hybrid designs. They are usually high-end devices ideal for centers with a sufficient volume of patients for SWL and endourology. Due to the optimal integration and synchronization of their high-end components to a synergistic system these machines offer maximal versatility in targeting and positioning for SWL. Uro-table function usually is excellent and offers great comfort in the performance of endourologic procedures. Ideally the patient table is entirely radiotransparent, accessible over 360°, and capable of bearing obese patients. The high investment cost and the fixed installation in a dedicated endourology/ESWL room may prohibit its acquisition in centers with limited patient loads.

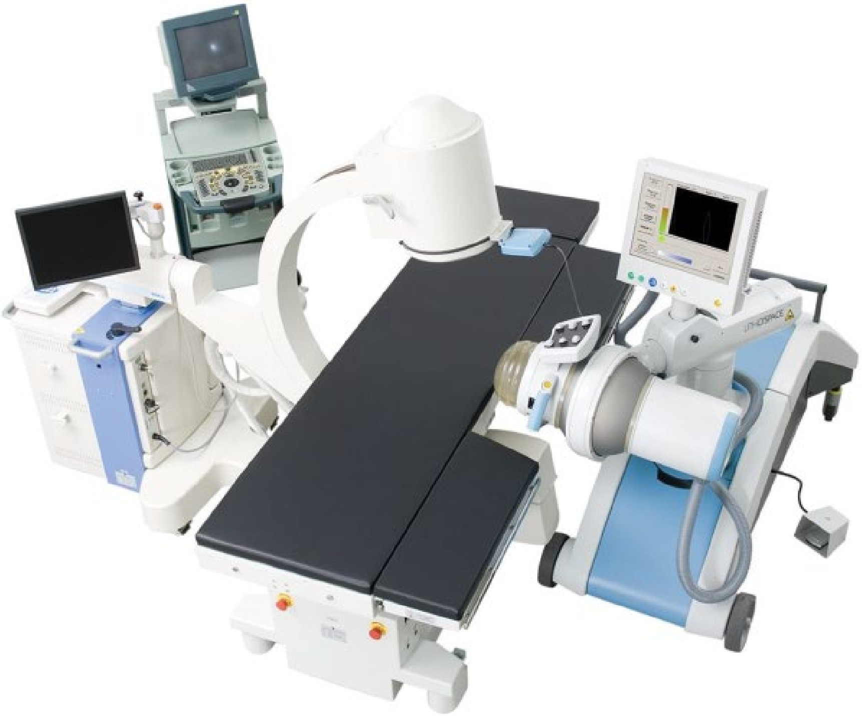

**Figure 59.1** Modular design: Jena Med Tech Lithospace. Reproduced with permission of Jena Med Tech GmbH.

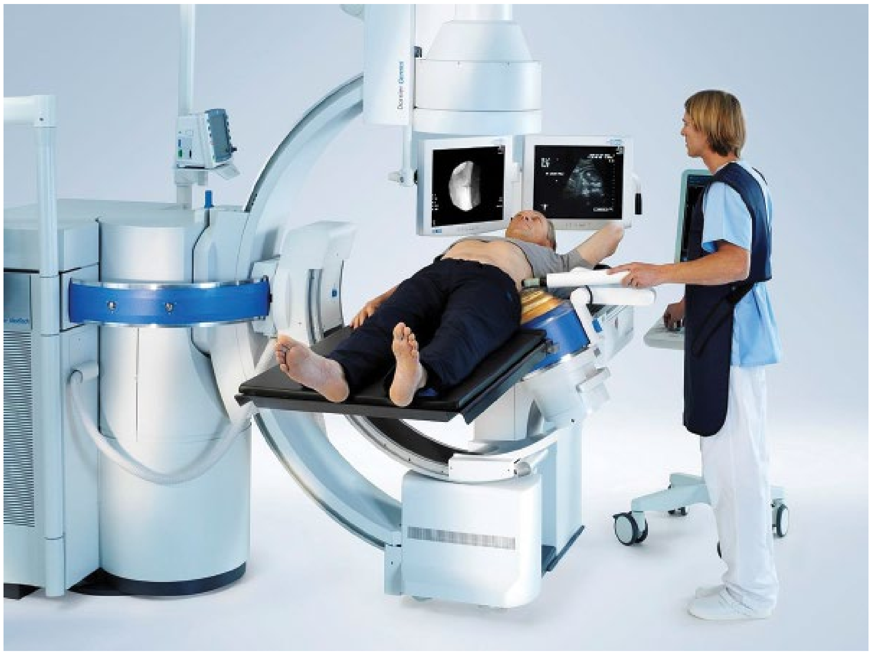

**Figure 59.2** Integrated design: Dornier Gemini. Reproduced with permission of Dornier MedTech GmbH.

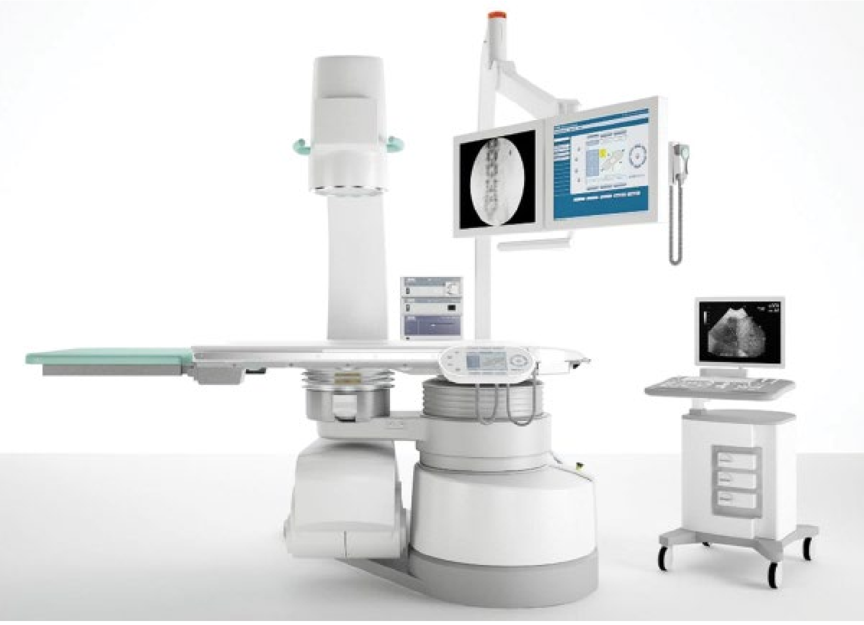

**Figure 59.3** Integrated design: Storz Modulith SLX-F2. Reproduced with permission of Storz Medical AG.

**Hybrid design**

In these machines imaging (fluoroscopy and/or ultrasound) and shock-wave source are mounted on a combined console (Figure 59.5). The patient treatment table is a stand-alone component to be added to the system for SWL or endourological procedures. Both investment cost and footprint are medium, i.e. between that of a machine with integrated design and a device with modular design. These systems are easily transportable and do not need a dedicated room. Some of the components (imaging, patient table) are suited for multifunctional and multidisciplinary usage. Uro-table function usually is adequate and overall handling is in between the modular and the integrated design.

## Performance of lithotripters

To measure the performance of a lithotripter, formulae have been devised that take into account stone-free rate, retreatment rate, and auxiliary procedure rate. The

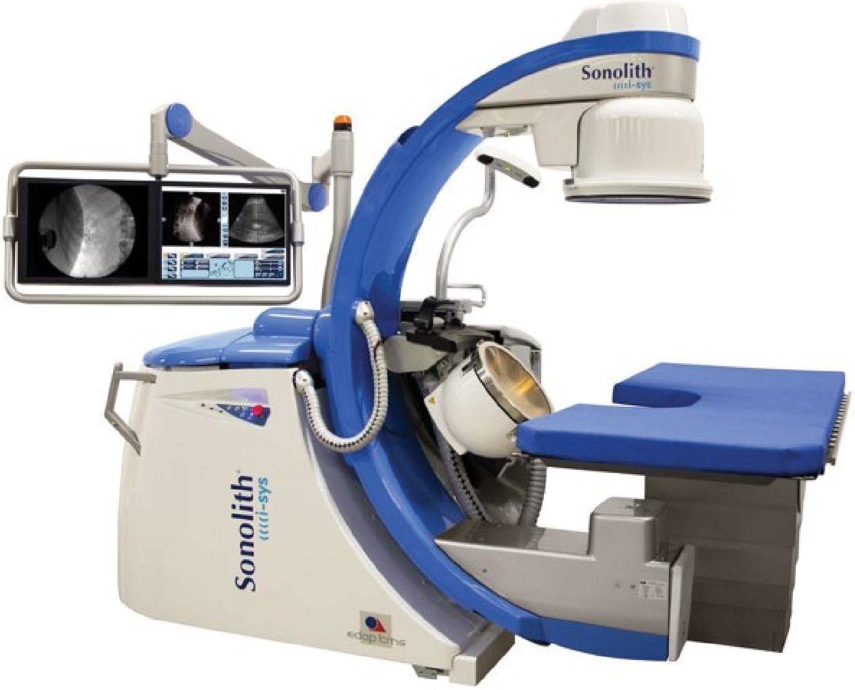

**Figure 59.4** Integrated design: EDAP TMS Sonolith i-Sys. Reproduced with permission of EDAP-TMS France.

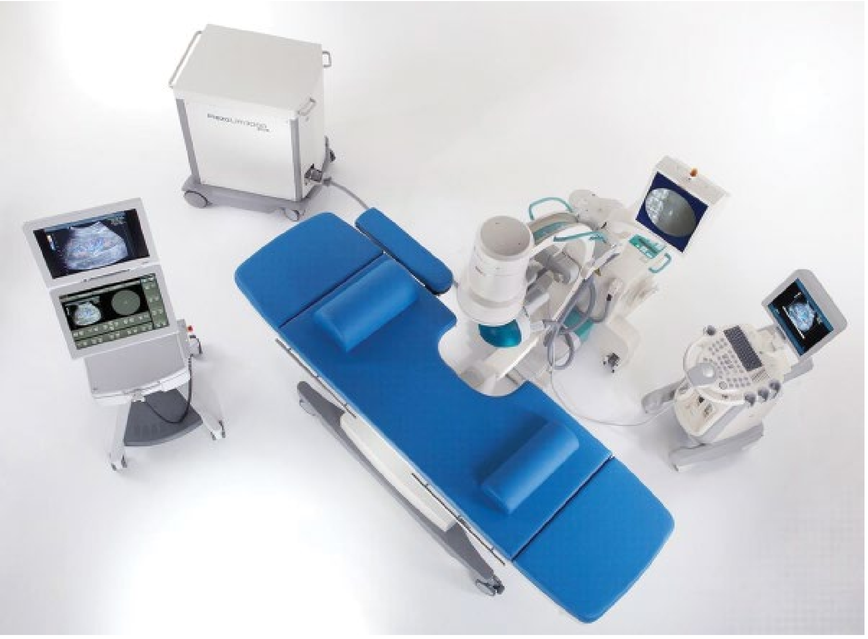

**Figure 59.5** Hybrid design: Wolf Piezolith 3000 plus. Reproduced with permission of Richard Wolf GmbH.

original effectiveness quotient ($EQ_A$) was defined by Denstedt, Clayman and Preminger [7, 41]:

$$EQ_A = \frac{\%\,\text{Stone} - \text{free patients}}{100\% + \%\,\text{retreatment} + \%\,\text{auxiliary procedures post–ESWL}} \times 100$$

The “extended EQ” or $EQ_B$ [10] and the “modified EG” or $EQ_{mod}$ [10] were defined in order to fine tune the performance estimations.

$$EQ_B = \frac{\%\,\text{Stone–free patients}}{100\% + \%\,\text{retreatment} + \%\,\text{auxiliary procedures pre–and post–ESWL}} \times 100$$

Modified EQ :

$$EQ_{mod} = \frac{\%\,\text{Stone–free patients} - \%\,\text{curative auxiliary procedures}}{100\% + \%\,\text{re–ESWL} + \%\,\text{pre–ESWL auxiliary procedures} \ + \%\,\text{post–ESWL auxiliary procedures}} \times 100$$

Although these formulae represent a mathematic tool to quantify and compare the performance of lithotripters, they only quantify stone-free rate, auxiliary procedure rate, and retreatment rate. A number of other factors are not readily quantifiable, but do play an important role in the final outcome of stone management by SWL: shock-wave source, stone burden, stone impaction, imaging modality and quality, targeting, analgesia regimen, shock-wave coupling, shock-wave release frequency, treatment strategy, and last but not least experience of the operator.

Treatment strategies and experience and skill of the operator have long been underestimated in the performance of SWL. Operator skill and experience unquestionably are key factors in success in SWL, however. Although newer electromagnetic machines perform at least equally good or even better than the HM3 the unmodified Dornier HM3 is still considered the gold standard in SWL. Results with newer lithotripters are, often erroneously, claimed to be poorer than with the original HM3 and many urologists therefore tend to shift to endourologic techniques in several indications.

Factors in the poorer results with modern lithotripters without a doubt are:

- Complexity of shock-wave administration is generally underestimated, especially by new users: lack of background and training in SWL is often the cause of poorer results with modern machines.
- HM3 users were extensively trained prior to certification.
- Newer machines are too often misjudged as “plug-and-play” with little attention paid to proper training of new users.

In order to improve results and reduce complication rate all (new) users of shock-wave machines should be certified on the basis of:

- a theoretical understanding of the basic physics of shock waves
- an extensive training in imaging, positioning and targeting, coupling, and treatment strategies
- a comprehensive understanding of shock-wave complications and the ways to avoid complications and improve results.

Although lithotripter manufacturers are directing extensive research towards improvements in focal geometry and energy to improve stone disintegration and at the same time reduce collateral damage to the surrounding tissue, together with urology training centers they should also invest in proper training of lithotripter users.

These coordinated efforts could and should lead to a renaissance of SWL as a valuable treatment of choice for urolithiasis at all levels of the urinary tract.

## The ideal lithotripter

An “ideal” lithotripter would have to have a high-performance shock-wave source producing a spherical focus exactly matching the size of the targeted stone and with the following energy requirements:

- moderate positive peak pressure, $p+$
- sufficient disintegration power (effective energy, $E_{12mm}$) to disintegrate hard stones and to compensate for shock-wave attenuation (obesity)
- minimal cavitation effects and hence minimal risk of adverse tissue effects.

Apart from producing a shock wave with the ideal focus, this high-performance shock-wave source would also have to meet the following requirements: prolonged lifetime without degradation or significant fluctuations of acoustic energy, wide range of energy settings, and adequate treatment depth (minimum 150 mm) to accommodate the ever-increasing proportion of obese patients, easily incorporated in a multifunctional device.

These requirements would almost automatically exclude conventional electrohydraulic sources: the lifetime of the electrodes is limited and the degradation of the electrode tips leads to output variations and instabilities of focal point and energy.

Coupling of the therapy head containing the shock-wave source is an important issue. The water cushion needs to be made of a material that easily adapts to the body curves and that causes minimal absorption, reflection, or refraction of the travelling shock wave.

Ideally the therapy head should incorporate a video camara for optical coupling control

(Figure 59.6). Optical coupling control results in a reduction of the total energy needed to fragment a stone. At the same time this theoretically could result in less shock-wave-induced adverse tissue effects.

Apart from that, the possibility to couple the treatment head to the patient both in an above- and an undertable position (Figure 59.7) is a very important asset, specifically in the *in situ* treatment of ureteral stones and especially in obese patients.

Accurate targeting is key to success in SWL and depends on excellent image quality, both fluoroscopic and ultrasonic. In endourologic procedures image quality is equally important.

A large image intensifier (up to 40 cm) offers a large view of nearly the entire urinary tract without the need to move the patient table. Orbital isocentric movements of the X-ray C-arm may prove useful in targeting in SWL. Full digitization of the X-ray imaging chain guarantees excellent image quality at low radiation dose. Digitization also allows easy and efficient storage of the images in the patient's records (DICOM capability). In newer lithotripters FPDs replace the traditional image intensifiers.

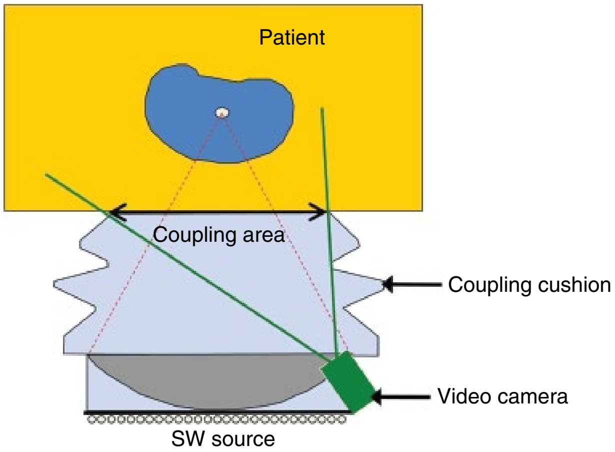

**Figure 59.6** Optical coupling control. SW, shock wave. Reproduced with permission of Dornier MedTech GmbH.

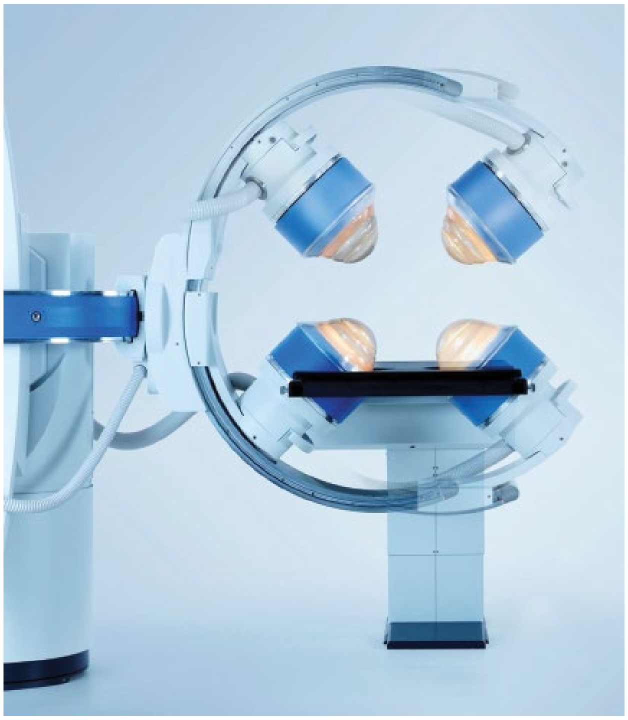

**Figure 59.7** Bilateral over- and undertable position of the therapy head (Dornier Gemini). Reproduced with permission of Dornier MedTech GmbH.

Increasing awareness of radiation safety and dose reduction and the excellent image quality of modern ultrasound machines make ultrasound an ideal tool for stone targeting and real-time monitoring of the entire treatment. An ideal lithotripter thus should be equipped with excellent imaging, both fluoroscopic and ultrasonic, preferably to be used online and simultaneously.

Another key component of a modern multifunctional lithotripter is the patient table. An ever-increasing number of obese and even morbidly obese patients demand a table with a high load capacity. To allow good imaging the tabletop needs to be radio-transparent. Finally, in endourologic procedures such as percutaneous nephrolithotomy and nephrostomy tube placement, maximum accessibility (ideally 360°) of the table from all sides is extremely important.

Good imaging and a careful urologist may provide accurate targeting, but respiratory movements continuously swing the targeted stone in and out of focus. A hit-and-miss system, that would keep track of the stone during respiratory movements and would only release a shock wave when the stone is exactly in the focus, would improve outcomes and at

the same time reduce collateral damage to the surrounding tissue. It would of course also slow down treatment. According to newer insights, however,

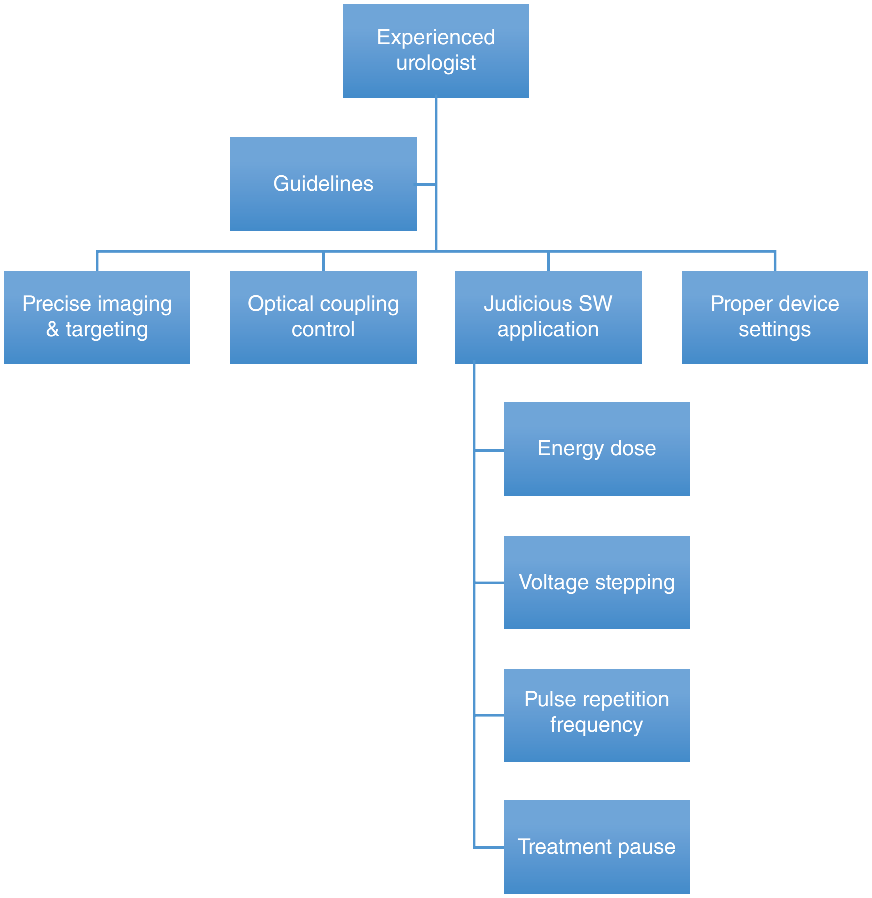

**Figure 59.8** Elements of "good lithotripsy." SW, shock wave.

slowing down treatments not only improves treatment efficiency [42, 43], but also reduces overall treatment cost [44].

Finally, this sophisticated piece of equipment should only be operated by an interested and experienced urologist, who has a basic understanding of the physics of shock waves [11, 31] and who is closely involved in all treatment modalities (SWL, percutaneous nephrolithotomy, ureterorenoscopy, robot-assisted retrograde intrarenal surgery) of modern stone management.

A department of urology looking for the ideal lithotripter should also invest in good clinical practice and "good lithotripsy" (Figure 59.8). The actual choice of the ideal lithotripter for any given stone center will depend on the specific requirements of a specific setting. A multifunctional workstation for SWL and endourologic procedures is the best choice for centers with an adequate patient load in both treatment modalities. An integrated or hybrid design makes economic sense in very active stone centers. In centers with a modest patient load a modular system may probably be the better choice. Our own stone center functions 5 days a week with a patient load of approximately 3000 treatments per year (500 ESWL and 2500 endourologic procedures). We try to solve any acute stone problem within 24 hours of admission, preferably on an outpatient basis. The centerpiece of this "integrated endourology concept" is a high-end multifunctional lithotripter with integrated design.

## Summary

The number of manufacturers and machines currently on the market prohibits an attempt to provide a complete overview of all systems available at present. Also, companies and machines come and go. Therefore this overview (see Tables 59.1–59.5) was limited to those traditional companies that were and still are very much involved in the development of and continued research in SWL. An exception to this rule was made for lithotripters designed with a philosophy derived from the theories of Eisenmeyer [29, 30]: wide focus, low focal pressure (Tables 59.6 and 59.7). Through their product managers most of these companies were very forthcoming in providing information, technical details, and illustrations for this chapter.

See accompanying Video 59.1.

# Shock-wave Lithotripsy of Renal Calculi

*Brian H. Eisner & Naren Nimmagadda*

*Department of Urology, Massachusetts General Hospital, Boston, MA, USA*

## Introduction

Once Chaussy and colleagues introduced extracorporeal shock-wave lithotripsy (SWL) in 1980, SWL spread to other institutions by 1984 and subsequent series confirmed success rates upwards of 90% using the Dornier HM3 lithotripter [1, 2]. Over the ensuing two decades, SWL became the most common procedure for urinary stone disease; by 2005, SWL accounted for 52% of all stone treatments in the United States [3]. Modern lithotripters have eliminated the water bath as a coupling agent, improving accessibility and patient comfort. SWL success rates now range from 48 to 65% but with greater need for auxiliary procedures than before [4, 5]. In this chapter, we present factors and techniques that allow safe and effective treatment of renal stones using SWL.

## Preoperative evaluation

A thorough history and physical examination is crucial for proper patient selection. Urine analysis is necessary for all patients and, if the concern arises for urinary tract infection, urine culture must be obtained [6, 7]. Optional laboratory studies include pregnancy testing when appropriate and coagulation studies for patients with history of coagulopathy. Regarding preoperative imaging, historically, renal ultrasound and plain abdominal radiography (i.e. kidney–ureter–bladder, KUB) were used to confirm stone presence, and intravenous pyelogram (IVP) was used to predict SWL success. However, with computerized tomography (CT) now universally available, noncontrast CT is the preferred imaging of choice [6–8]. Though not absolutely necessary, CT has the advantage of allowing the urologist to assess for factors predictive of SWL success, which will be discussed later in this chapter.

## Absolute contraindications

Box 60.1 lists types of patients in whom SWL is contraindicated. These conditions are described below.

### Pregnancy

SWL is prohibited in pregnant women [8]. Though a small series reported on six females treated safely early during pregnancy [9], animal experiments in mice have shown deleterious effects of shock waves on the mouse fetus, affecting viability [10].

### Anticoagulants or uncorrected bleeding diathesis

Patients in whom anticoagulant/antiplatelet agents cannot be held or reversed, and in whom coagulopathy cannot be controlled, should not be treated with SWL. Expert opinion concludes that bleeding diathesis should be controlled for 24 hours before and 48 hours postprocedure [8]. Renal hematomas are reported to occur in 1% of patients *without* coagulopathy after SWL [11]. The literature on SWL in individuals with iatrogenic and/or pathological bleeding diathesis is sparse, retrospective, and nonstandardized, however [12]. Continuation of aspirin during SWL has been reported but with mixed results [12]. A fourfold increase in the risk of postoperative hematoma was reported in one study when antiplatelet agents (aspirin/nonsteroidal anti-inflammatory drugs) were continued during SWL: these patients were managed conservatively [11]. SWL in patients taking clopidogrel has been associated with cases of nephrectomy and death [13, 14]. Other reports looking at all causes of bleeding diathesis including pathologic conditions

**Box 60.1 Absolute contraindications to SWL.**

Pregnancy
Uncontrolled bleeding diathesis
Uncontrolled hypertension
Untreated infection
Significant skeletal malformations or severe obesity
Arterial aneurysms in close proximity to target stone

such as hemophilia, von Willibrand disease, etc., suggested hematology consultation and consideration of SWL only if the coagulopathy can be corrected [15].

### Uncontrolled hypertension

Uncontrolled hypertension has been associated with an increased risk of renal hematoma after SWL and should be controlled prior to treatment [8]. The incidence is as high as 4.3% in this group [16]. Intraoperative hypertension (defined as blood pressure >140/90 mmHg) is also a significant risk factor for hematoma formation with a threefold increase in risk [11].

### Arterial aneurysms in close proximity to the targeted stone

Aortic or renal artery aneurysms near the renal stone are listed as contraindications to SWL [8]. Aortic aneurysm rupture is described after SWL in five case reports [17]. Calcified plaque within the aneurysm may be fragmented by shock waves leading to rupture. These case reports are in contrast to *in vitro* studies showing SWL does not significantly damage human calcified aneurysm tissue [18]. Some authors concede that SWL can be performed in the setting of arterial aneurysms provided that the patient is monitored [17].

### Severe skeletal malformations or obesity

Certain skeletal malformations may prevent positioning of the patient on the lithotripter table [8]. Severe obesity may pose a similar issue and can also make visualization of the stone difficult under fluoroscopy or ultrasound.

### Anatomical or functional obstruction of the urinary tract

Any patient with anatomic or functional ureteropelvic junction or ureteral obstruction distal to the stone should not undergo SWL [6–8]. These abnormalities may delay or impede clearance of residual fragments and lead to significantly lower stone-free rates [19].

### Untreated cystitis, pyelonephritis, or bacteriuria

Patients with untreated cystitis, pyelonephritis, or bacteriuria are at risk of worsening infection and/or urosepsis during SWL. These patients should undergo proper antibiotic treatment first [6, 7].

## Stone characteristics

Early experience demonstrated that stone composition influences SWL success. Dretler first described "stone fragility": stones of various compositions have differing susceptibility to shock waves [20]. Subsequently, Dretler described stone breakability or "stone durility" [21]. Cystine, brushite, and calcium oxalate monohydrate stones are the least fragile (i.e. most durile) while uric acid stones are the most fragile [22]. This can be seen *in vitro* (Figure 60.1); however, the standard deviation of shocks required for each stone type is large, indicating variability in fragility within stones of the same composition [23]. Because of this variability, stone composition is less important in predicting SWL success than other factors such as Hounsfield density, which will be discussed later in this chapter. Secondary mineral composition, spatial arrangement of various mineral components, and variations in layer structures of different mineral components also affect stone fragility [23].

## Imaging characteristics

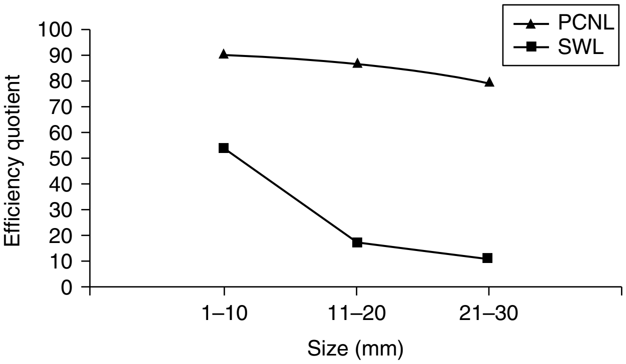
Multiple factors obtained from preoperative imaging are useful for patient selection. While stone size and location can be gathered from plain abdominal radiography or renal ultrasound, Hounsfield density, pelvicalyceal anatomy, and skin-to-stone distance are only available with CT imaging.

### Stone size and location

Stone size and location are the most influential factors in determining the management of renal stones. SWL stone-free rates at 3 months are quoted to be 86–89% for renal pelvis, 71–83% for upper calyx, 73–84% for middle calyx, and 37–68% lower calyx stones across several generations of lithotripters [24]. A critical review of SWL outcomes for lower pole stones first published in 1994 reported stone-free rates of 60% after one treatment. When broken down by stone size, stone-free rates for stones <1, 1–2, and >2 cm were 74, 56, and 33%, respectively [25]. The general consensus is that individuals with stones >2 cm in the upper and middle calyces and >1 cm in the lower calyx should not be offered SWL as first-line therapy [6, 7]. Subsequent studies of newer generation lithotripters have demonstrated lower success rates than initial studies; 3 month stone-free rates for the second-generation Dornier MFL5000 for lower pole stones were 56% [26], and overall stone-free rates for the third-generation Siemens Lithostar Plus were decreased by 40% when compared to the earlier Dornier HM3 [4]. Finally, the fourth-generation Storz Modulith (SLX-F2) lithotripter was found to have equivalent stone-free rates for solitary renal stones compared to the HM3 but required significantly more shocks to achieve this [27].

Incomplete fragmentation can lead to steinstrasse, which is a column of stone fragments that lodge within the ureter causing obstruction after SWL [28, 29]. The word *steinstrasse* is German for “stone street” which refers to the radiographic appearance of this condition. Steinstrasse occurs when the lithotripter fragments the stone into pieces that are not easily passed spontaneously [28]. Size and location are two independent risk factors for this to occur [28, 29]. SWL performed on renal stones is 2.7 times more likely to cause steinstrasse than ureteral stones [28]. Incidence rates for steinstrasse after SWL for renal stones <1, 1–2, and >2 cm were 4.4, 15.7, and 24.3%, respectively. This study also found renal pelvis stones to be a significant predictor of steinstrasse compared with calyceal stones [29].

To date, five randomized controlled trials (RCTs) have evaluated SWL versus other endourological procedures [24]. The two highest quality, RCTs evaluated lower pole stones [30, 31]. The first multicenter study evaluated the efficacy of SWL versus percutaneous nephrolithotomy (PCNL). Of note, multiple generations of lithotripters were used across the institutions. Stone-free rates were significantly higher with PCNL for every stone size (<1, 1–2, and >2 cm), and for stones >1 cm only 21% of patients became stone-free with SWL. Retreatment and auxiliary procedure rates were significantly lower for PCNL. SWL had an acceptable 50% efficiency quotient for stones <1 cm versus an efficiency quotient of less than 20% for stones >1 cm (Figure 60.2). The authors concluded that as stone size increases beyond 1 cm, the likelihood of becoming stone-free with SWL decreases significantly and that SWL is suitable only for lower pole stones <1 cm [30]. A follow-up multicenter trial randomized 67 patients with lower pole stones <1 cm to either ureteroscopy or SWL. There was no significant difference in 3 month stone-free rates or the need for secondary procedures between the groups, supporting SWL as an acceptable first-line therapy for lower pole stones <1 cm in size [31].



$$\text{EQ} = \frac{\%\ \text{Stone free}}{100 + \%\ \text{retreatment} + \%\ \text{auxiliary procedures}} \times 100$$

**Figure 60.2** Efficiency quotients for SWL and PCNL for lower pole calculi stratified by stone size. *Source:* [30]. Reproduced with permission of Elsevier.

### Lower pole pelvicalyceal anatomy

Sampaio and Aragao described an angle between the lower pole infundibulum and renal pelvis <90°, diameter of the lower pole infundibulum <4 mm, and multiple lower pole calyces as risk factors for poor stone clearance after SWL [32]. Subsequent studies have described less acute infundibulopelvic angle, shorter infundibular length, and increased infundibular width of the lower pole as being associated with increased likelihood of stone clearance. Elbhanasy and colleagues correlated stone clearance after SWL in patients with lower pole stones using preoperative IVP, identifying fixed landmarks that allowed for reproducible measurements [33].

Lower pole infundibular length, width, and infundibulopelvic angle were defined very precisely as illustrated in Figures 60.3–60.5, respectively. Their study found that an infundibulopelvic angle >90°, infundibular length <3 cm, and infundibular width >5 mm were all significant predictors of stone-free status [33]. Subsequent studies have yielded equivocal results. In the two most commonly cited RCTs evaluating SWL versus ureteroscopy or PCNL in lower pole stones, neither infundibulopelvic angle, infundibular length, nor infundibular width were found to be statistically significant predictors of SWL success [30, 31].

## Hounsfield density

Chaussy and Fuchs originally compared a stone's radiodensity to that of the spine and hypothesized that if the stone was less dense than the spine, the stone should fragment more easily [34]. Today, Hounsfield units (HU) measured using CT can be used to determine a stone's radiodensity. These values should be obtained using bone windows, in a dimension with the widest stone diameter and in a manner so as to include the largest cross-sectional area of stone without including adjacent tissue [35]. Numerous studies have shown a stone's Hounsfield density value to be predictive of SWL success. The higher the CT attenuation value, the more

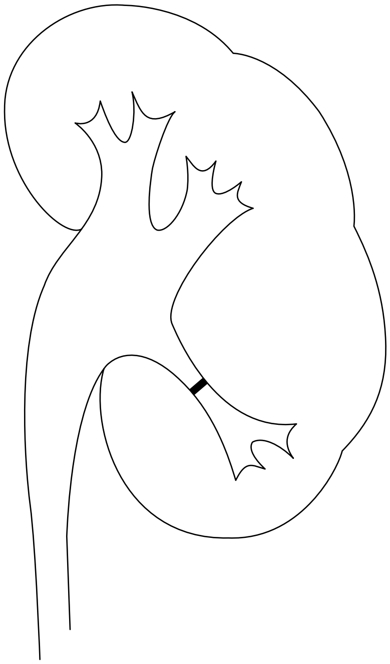


**Figure 60.4** Lower pole infundibular width is measured at the narrowest point along the infundibular axis. *Source:* [33]. Reproduced with permission of Elsevier.

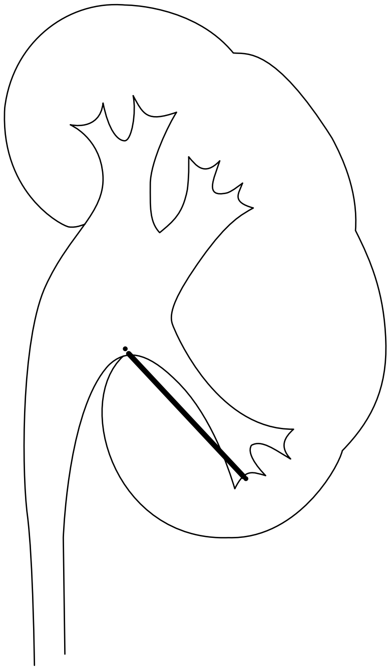

**Figure 60.3** Lower pole infundibular length is measured between the most distal point at the bottom of the infundibulum to a midpoint at the lower lip of the renal pelvis. *Source:* [33]. Reproduced with permission of Elsevier.

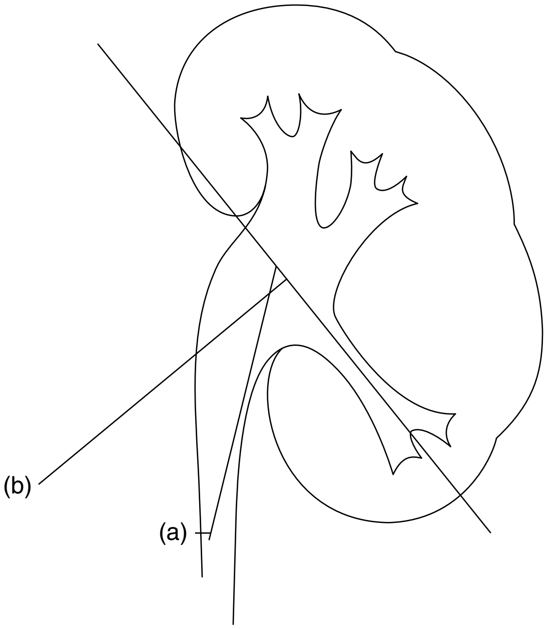

**Figure 60.5** Lower pole infundibulopelvic angle is defined as the angle between two axes: the ureteropelvic axis created by connecting the central point of the renal pelvis opposite the margins of the superior and inferior renal sinuses to the central point of the ureter opposite the lower pole (angle a), and the central axis of the lower pole infundibulum (angle b). *Source:* [33]. Reproduced with permission of Elsevier.

likely SWL will fail. SWL should not be considered when CT attenuation values are greater than 900–1000 HU [6, 7]. Joseph and colleagues studied Hounsfield density in patients undergoing SWL for renal stones <2 cm in size. SWL required a greater number of shock waves as Hounsfield density increased and failed more often in patients specifically when the Hounsfield density of the stone was >1000 HU [36]. Other groups identified a cutoff of 900 HU [35, 37]. One particularly striking study found CT attenuation values <970 HU correlating with a 96% success rate while 62% of patients above that threshold failed treatment [38]. It is important to note that CT attenuation values may be falsely low for smaller stones and are more accurate for larger stones [35]. Likewise, low-dose versus standard dose CT with various collimation widths will also affect CT attenuation values [39].

### Skin-to-stone distance

Skin-to-stone distance (SSD) – i.e. the distance between the stone and the skin – was originally described by Pareek and colleagues [40]. SSD was measured by averaging the distance between the center of the stone and the skin at 0, 45, and 90° from a horizontal line drawn through the stone on axial CT images (Figure 60.6). They found a mean SSD of 8.12 ± 1.74 cm in those patients who became stone-free versus 11.53 ± 1.89 cm in those patients with residual stone ($P < 0.01$) [40]. SSD was a more accurate predictor of SWL success than body mass index in their study. An SSD cutoff of 10 cm is associated with the optimal sensitivity and specificity [40].

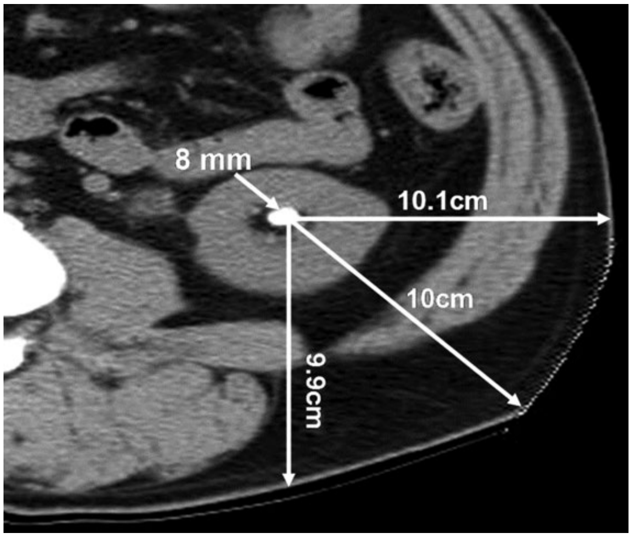

**Figure 60.6** SSD is measured by averaging the distance between the center of the targeted stone and the skin at 0, 45, and 90° from a horizontal line drawn through the stone on axial cuts of a CT. *Source:* [40]. Reproduced with permission of Elsevier.

### Predictive models of shock-wave lithotripsy success

The first SWL mathematical model was created by Vakalopoulos in 2009 after retrospectively reviewing 1997 renal and ureteral stones treated by SWL [41]. The equation $P = 1/1 + e^{-z}$ was used to predict SWL success where $Z$ varies based on the location of the stone. This coefficient for renal stones equals the equation below with the variables determined from Table 60.1:

$$\begin{aligned} Z = 0.95 + 0.24X_1 + 0.77X_2 + 1.18X_3 - 0.61X_4 \\ - 0.72X_5 - 10X_6 + 0.75X_7 + 0.12X_8 + 0.98X_9 \\ + \text{location coefficient}X_{10} \end{aligned}$$

Their model was predictive 85.3% of the time for patients with renal stones in their cohort. Of note, the presence of a stent was not a significant predictor of SWL success. In addition, only 10% of patients had a preoperative CT [41].

**Table 60.1** Variables to be used in the mathematical model for prediction of SWL outcome for urinary stones by Vakalopoulos. Reproduced with permission of Mary Ann Liebert, Inc.

| Variable | Value | Description |
|---|---|---|
| $X_1$ Sex | 0 | Female |
| | 1 | Male |
| $X_2$ Age | 0 | ≤40 and ≥61 years |
| | 1 | 41–60 years |
| $X_3$ Body mass index | 0 | ≤20.0 and ≥28.1 kg/m$^2$ |
| | 1 | 20.1–28.0 kg/m$^2$ |
| $X_4$ Stone size | 0 | ≤10 mm |
| | 1 | >10 mm |
| $X_5$ Stone volume | 0 | <0.5 cm$^3$ |
| | 1 | >0.5 cm$^3$ |
| $X_6$ Stone density | 0 | ≤Bone density |
| | 1 | >Bone density |
| $X_7$ Number of stones | 0 | Multiple stones |
| | 1 | Simple stone |

| | 3 | Upper calix |
| | 4 | Middle calix |
| | 5 | Lower calix |

UPJ, ureteropelvic junction.

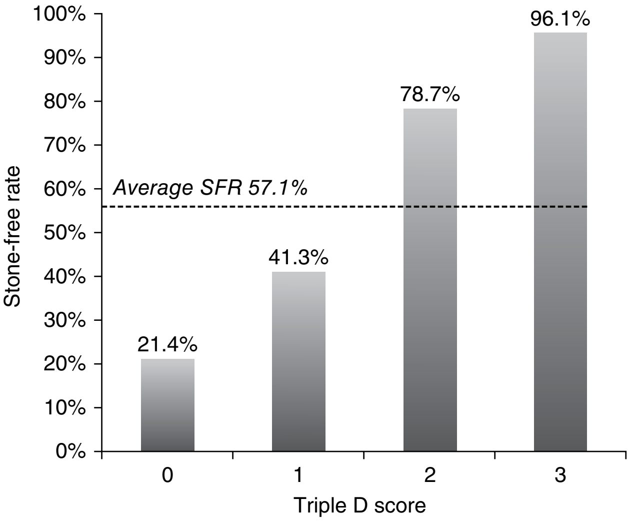

**Figure 60.7** Stone-free rate (SFR) according to Triple D score. 57.1% of patients were stone-free on KUB/renal ultrasound obtained after 4–6 weeks overall. *Source:* [42]. Reproduced with permission of Mary Ann Liebert, Inc.

More recently, the Triple D score was created using factors identifiable on CT for renal or ureteral stones >4 mm in size [42]. SSD (distance), stone attenuation (density), and ellipsoid stone volume (ESV) (dimensions) were found to be significant predictors of single treatment success. To determine the Triple D score, a point is added when ESV is <150 μl, stone attenuation is <600 HU, or SSD is <12 cm [42]. Patients in the study with all three favorable characteristics had a 96.1% single treatment stone-free rate (Figure 60.7).

## Preoperative considerations

### Antibiotic prophylaxis

A recent meta-analysis included 1364 patients with sterile preoperative urine from nine RCTs to examine the effect of antibiotics on post-SWL rates of urinary tract infection. There were no significant differences in symptoms, rate of fever, rate of positive urine culture, and incidence of urinary tract infections (symptoms + urine culture) if prophylactic antibiotics were given. Culture proven urinary tract infection rates after SWL ranged from 0 to 14% of patients across the included studies [43]. Antibiotic guidelines between the European Association of Urology and American Urological Association are now similar and recommend that in the absence of urinary tract infections or other risk factors (external catheters, suspected infected stones, etc.) with documented sterile urine, antibiotic prophylaxis prior to SWL is not indicated [6–8]. When prophylaxis is necessary, antibiotic selection should be based on previous urine or stone cultures and local antibiograms.

### Routine preoperative stenting

Routine preoperative stenting was historically practiced by many urologists to facilitate passage of stone fragments and prevent ureteral obstruction after SWL. However, modern data suggest otherwise. When data from multiple RCTs was pooled in a meta-analysis of 453 patients, the total stone-free rate in those who were stented preoperatively was 78.1 versus 83% in the stentless group ($P = 0.27$). The presence of a stent also does not prevent renal colic, steinstrasse, or additional procedures [44]. Current guidelines no longer recommend routine preoperative stenting; however, prior guidelines (i.e. European Association of Urology 2010 guidelines) recommended stenting prior to SWL of large stones (i.e. >2 cm) [6–8].

## Shock-wave lithotripsy technique

### Shock-wave number and rate

In an effort to maximize stone fragmentation and minimize trauma to the kidney and surrounding structures, variations in the administration of shock waves have been methodologically studied. There are no conclusive data to recommend an optimum number of shock waves [8]; however, most surgeons apply 2000–3000 shock waves [45]. The association between slower shock-wave rate and improved stone fragmentation was described in an *in vitro* study in 1989 after applying 3000 shock waves from a piezoelectric generator to explanted human kidney stones at frequencies ranging from 75 to 600 shocks/minute. Stones treated at the lower rates of 75 and 150 shocks/minute achieved better fragmentation [46]. This effect is thought to be from the interaction of cavitation bubbles: at slower shock-wave rates, a greater proportion of cavitation bubbles will contact the stone, resulting in fragmentation. At faster shock-wave rates, cavitation bubbles may interact with one another as opposed to the stone surface [47]. The negative pressure phase of a shock wave specifically becomes dampened at a faster rate (Figure 60.8); this phase is responsible for the tensile stress induced on a stone. The positive pressure phase of the shock wave is not affected by a faster rate [48].

RCTs have shown that optimal SWL frequency is 60–90 shocks/minute. Three month stone-free rates were found to be significantly better when SWL was performed at 60 versus 120 shocks/minute [49]. Subsequently, a rate of 90 shocks/minute was shown to have significantly better

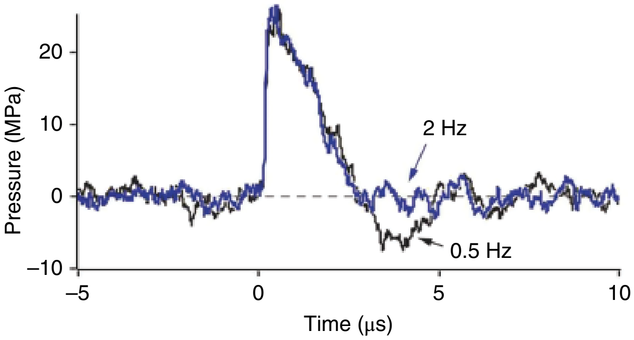

**Figure 60.8** Pressure wave generated from shock waves applied at 0.5 Hz (30 shocks/minute) and 2 Hz (120 shocks/minute) *in vitro* to stones placed in a basket in the focal zone of a laboratory lithotripter modeled from a Dornier HM3. The positive pressure phase is the same but the negative pressure phase is dampened when shock waves are applied at 2 Hz (120 shocks/minute). *Source:* [48]. outcomes than 120 shocks/minute [50]. A recent meta-analysis of nine RCTs with a total of 1572 patients confirmed that frequencies of 60 and 90 shocks/minute yielded equivalent success rates and both were significantly better than 120 shocks/minute [51]. An additional meta-analysis noted that the benefits of a slower shock-wave rate are most notable for stones >10 mm [51]. While slower shock-wave rates were associated with decreased renal injury in porcine models of SWL [52, 53], no differences in complications due to shock-wave rate were observed in human trials [51].

## Pretreatment

Pretreatment is the application of low-energy shock waves to the targeted renal stone in order to "prime the kidney" and reduce renal injury. Initial studies were done *in vivo* using porcine kidneys and the Dornier HM3 [54]. Willis demonstrated that when 2000 shock waves at 24 kV were applied to one pole of the kidney, the hemorrhagic lesion caused by 24 kV shock waves applied to the opposite pole immediately afterwards was smaller (Figure 60.9) [55]. A subsequent study evaluated 500 shock waves applied at 12 kV followed by standard SWL treatment on the same pole; this correlated with a 20-fold reduction in the size of the resultant hemorrhagic lesion when compared with no pretreatment [55]. More recently, 300 shock waves applied at 12 kV was also proven to significantly reduce the hemorrhagic lesion size [56]. While the exact mechanism is unknown, Doppler ultrasonography has shown that pretreatment is associated with renal vasoconstriction [57].

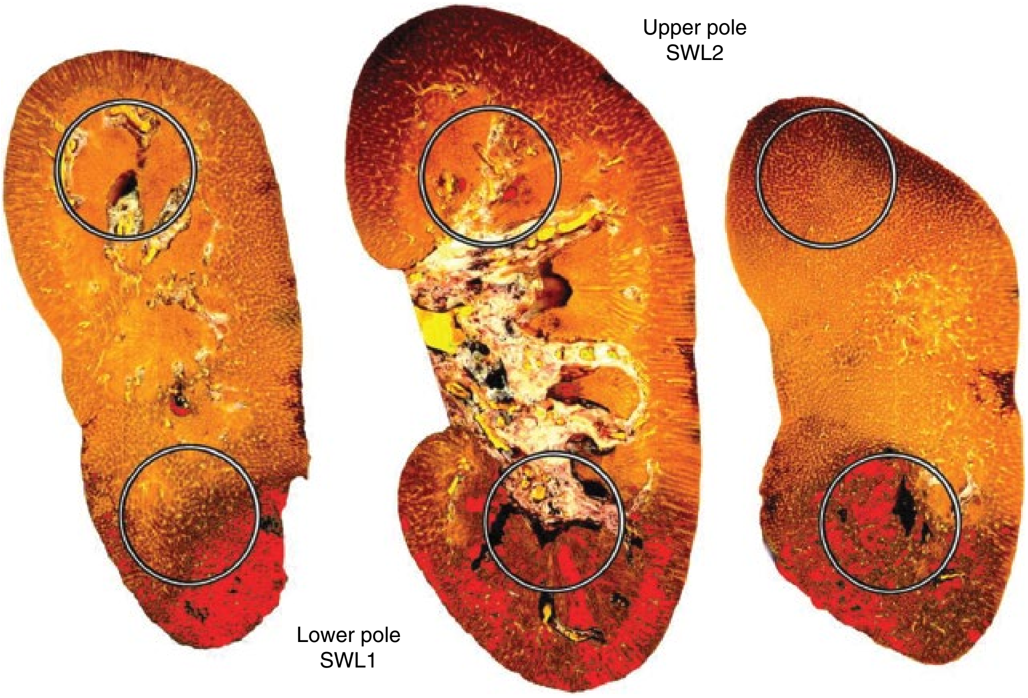

**Figure 60.9** Coronal sections of porcine kidney after the lower pole was first treated with 2000 shock waves at 24 kV followed by the same clinical dose applied to the upper pole. Circles denote the focal zone. Hemorrhagic lesions appear in red. There is significantly less hemorrhage in the second focal zone after the shock waves were applied to the first focal zone. Reproduced with permission of the American Society of Nephrology.

### Pretreatment time and pause

For the initial pretreatment studies, Willis needed a 3–4 minute gap between pretreatment and full-dose shock waves in order to retarget: this lead the authors to hypothesize that a pause during SWL may also reduce renal damage [53]. A pause was subsequently incorporated into all of their experiments. One protocol included pigs treated with 2000 shock waves continuously at 24 kV versus treatment with 100 shocks at 24 kV followed by a 3 minute pause and then an additional 2000 shocks at 24 kV, demonstrating that the 3 minute pause was associated with decreased hemorrhagic lesion size caused by SWL [53]. Further studies have noted that perhaps the greatest influence on reducing trauma is the cumulative time of low dose treatment plus pause. For example, 100 low-dose shock waves followed by a 10 second pause did not confer protection from injury whereas 500 low-dose shock waves followed by a 10 second pause showed a protective effect. It was theorized that the time it takes to administer 500 shock waves, or around 4 minutes, allows adequate time to sensitize the renal vasculature leading to stronger vasoconstriction during subsequent full-dose shock-wave treatment [58].

### Voltage escalation

Escalating shock-wave voltage improves stone comminution in a porcine model with the Dornier HM3 when compared with delivering all shock waves at the highest voltage dose [59]. Escalating the energy level is also thought to “prime” the stone for further fragmentation at higher energy levels [60]. Voltage escalation protocols for SWL have been evaluated in two RCTs in humans. The first trial looked at stepwise voltage increments from 11–13 kV every 500 shock waves versus 13 kV for 3000 shock waves using a Dornier Compact Delta machine. The stepwise escalation group had a 96% stone-free rate at 8 weeks versus 72% in the constant voltage group [61]. In a second double-blind RCT, shock waves were either delivered starting at 14–15 kV followed by immediate escalation every 10 shocks to 23 kV for a total of 3000 shock waves or 15 kV for 1000 shock waves followed by delayed escalation by 1 kV every 10 shocks to 23 kV for a total of 3000 shock waves using a Philips LithoTron machine. Single treatment success at 3 months was 72.5% in the immediate escalation group versus 54.5% in the delayed escalation group ($P = 0.021$) [60]. It is important to consider that in the delayed escalation group, approximately half of the shock waves delivered were at low energy. While many agree that voltage escalation will improve stone fragmentation, escalation must be done promptly enough to deliver a reasonable amount of shock waves to the stone at higher voltage.

### Cardiac arrhythmia, pacemakers, and implantable cardiac defibrillators

Shock waves can affect cardiac rhythm and alter pacemaker and implantable cardiac defibrillator function such that the application of shock waves may have to be adjusted. Arrhythmias were noted especially with first-generation lithotripters (up to 80% of procedures) and persist to a lesser degree with newer-generation machines [62, 63]. It is important to note that cardiac arrhythmias during SWL occur almost exclusively with treatment of renal stones and may be more likely to happen during treatment of the right kidney [64, 65]. To prevent arrhythmias most lithotripters can be switched to a “gated” mode in which a shock wave is initiated during the R wave of the electrocardiogram. Maximal heart effects will then occur during the heart’s refractory period [62]. If premature contractions are noted, pausing treatment long enough to resume normal heart rhythm may solve the problem; if not, then gating is recommended [64]. More recently, rotating the patient 15–20° away from the supine position was described as another maneuver to resolve an arrhythmia without having to gate shock-wave delivery [65].

Today, SWL is considered safe in individuals with these devices [8] and most manufacturers of pacemakers and implantable cardiac defibrillators have recommendations for lithotripsy [66]. Preoperative cardiology consultation may be of benefit for patients with implantable devices or history of arrhythmia.

## Adjunct therapy after shock-wave lithotripsy

### Percussion, diuresis, and inversion therapy

Several investigators have described adjunct techniques to improve stone clearance after SWL, especially for lower pole stones. The kidney lies in an oblique axis such that the upper pole is posterior to the lower pole. Inversion >30° below the horizontal plane allows optimal positioning of the collecting system for fragment expulsion from the lower pole [67, 68]. Diuretics and high volume fluid intake have also been tried in an effort to augment urine production and flush fragments out [69]. Lastly, percussion theoretically employs repetitive mechanical pressure on the flank to vibrate the renal system and discharge fragments in the augmented urine flow [67, 68]. One RCT of SWL for lower pole stones <2 cm in diameter tested a median of four sessions of diuresis, inversion, and percussion performed 1–2 weeks after each SWL plus additional sessions in those with persistent stone at

1 month following the last SWL. This involved drinking 500 ml of water 30 minutes prior to inversion in a prone Trendelenburg position at 45° and continuous manual mechanical percussion over the flank for 10 minutes [67]. Another RCT was limited to lower pole fragments <4 mm in diameter 3 months after SWL and involved 20 mg of furosemide followed by inversion to >60° and flank percussion using a mechanical chest percussor for 10 minutes. This was done weekly for 3 weeks or until stone-free [68]. Both trials demonstrated significantly improved stone-free rates using these adjunct techniques. Based on this evidence, the European Association of Urology recommends consideration of inversion, diuresis, and percussion for well-disintegrated lower pole stones [8].

### Medical therapy after shock-wave lithotripsy

Medications to augment the passage of fragments including α-adrenergic antagonists, calcium channel blockers, corticosteroids, and smooth muscle relaxants have been studied in over 20 RCTs [70, 71]. Pooled data have shown nearly twofold increases in stone-free rates as well as reductions in expulsion time, steinstrasse, and renal colic, with tamsulosin being the most-studied pharmacotherapy [6, 7, 71]. Therefore, use of these medications is endorsed by various guideline panels [6–8]. More recently, *Phyllanthus niruri*, a Brazilian plant remedy which prevents calcium oxalate crystal growth, was shown to improve stone-free rates after SWL of lower pole stones when compared with placebo in a RCT (93.7 vs. 70.8%, $P = 0.05$) and with no side effects reported [72].

Small residual fragments after SWL raise concern as a nidus for recurrent stone formation. In a RCT evaluating potassium citrate therapy after SWL for lower pole renal stones, individuals who were stone-free and prescribed potassium citrate had zero stone recurrences in the following 12 months. In those with residual stone fragments, a 44.5% reduction in stone recurrence was observed in patients prescribed potassium citrate versus 12.5% in those who were not [73].

## Patients with anatomic anomalies or varations

Outcomes of SWL in patients with anatomic variations are described here and in Table 60.2. These findings are from retrospective studies due to a lack of RCTs with such patients. It is important to note that 88% of the cases in these series required auxiliary procedures and/or retreatment including ureteral stenting or catheterization which was argued may augment the success rate in these patients [19].

### Horseshoe kidney

Horseshoe kidney is associated with anterior displacement of the renal pelvis and high insertion of the ureter which may impede stone clearance after SWL. Perhaps based on these anatomic factors, one of the largest reports of SWL for stones in horseshoe kidneys reported a 9.1% 3 month stone-free rate and 72.7% auxiliary treatment rate. In this study, upper calyceal location and increased body mass index were associated with poorer stone clearance [74]. To combat some of these issues, patients can be placed prone, reducing SSD and potentially improving urinary drainage [75].

**Table 60.2** Outcome of SWL based on anatomic anomaly or variation [19].

| | SWL outcome (%) | | |
|---|---|---|---|
| **Anomaly/variation** | **Stone-free** | **>90% clearance** | **Residual stone** |
| UPJ obstruction | 51 | 11 | 38 |
| Horseshoe kidney | 49 | 11 | 40 |
| Malrotation | 44 | 29 | 27 |
| Ectopic kidney | 77 | 10 | 13 |
| Calyceal diverticula | – | 45 | 55 |
| Duplicated ureter | 55 | 16 | 29 |
| Non-obstructive megaureter | 40 | 27 | 33 |
| Medullary sponge kidney | 6 | 12 | 82 |

UPJ, ureteropelvic junction.

### Ureteropelvic junction obstruction, megaureter, duplicated ureter with hydronephrosis

If SWL is to be attempted in patients with ureteral abnormalities, renal scintigraphy should be considered to rule out clinically significant obstruction. Three month stone-free rates for these anatomical variations in those without obstruction range from 40–55% [19].

### Malrotated kidney and ectopic kidney

Malrotated and/or ectopic kidneys may have impaired urinary drainage due to vascular compression of the ureter or ectopic location [76]. In the absence of obstruction, 3 month stone-free rates are reported to be 44% for malrotated kidneys and 77% for ectopic kidneys (mean pretreatment stone size 21 mm) [19].

### Calyceal diverticula

SWL stone-free rates for treatment of diverticular stones ranges from 0–25% [77]. A few reports suggest SWL may be useful for stones <1 cm in size only if there is a radiographically confirmed, short and patent diverticular neck which could allow fragment passage [77]. One study reported fluoroscopic evidence of stone fragmentation in 87% of patients but 3 month stone-free rates of only 21%. Of note, despite low stone-free rates, a majority of patients in this study (61%) reported resolution of pain and/or recurrent infection at 2 years mean follow-up [78].

### Urinary diversion

The incidence of renal stones in patients with colon conduits is 3–4% and with ileal conduits is 10–20% [79, 80]. Postulated mechanisms include metabolic acidosis/hypocitraturia due to urinary diversion, hyperoxaluria, chronic urinary tract dilation/reflux, and chronic or recurrent bacteriuria [81]. SWL is an attractive option in the absence of downstream ureteral obstruction as retrograde ureteroscopy may be challenging in these patients [81]. SWL monotherapy was found to have an 81.5% success rate in a small study with 27 patients with renal stones and urinary diversion. Two sessions were needed in 29.6% of patients, while 14.8% needed three sessions and 7.4% of patients developed obstruction from stone fragments requiring additional, more invasive procedures [82].

## Pediatric shock-wave lithotripsy

SWL has been used in the pediatric population since the 1980s and is widely considered safe [83, 84]. Stone-free rates after the treatment of renal stones in children are generally higher than in adults and range from 80 to 85% [6, 7, 84, 85]. The absolute contraindications are similar to adults. In contrast to adults, SWL for stones >2 cm in size, including staghorn calculi, can be effective and is acceptable in children [6, 7]. Stone-free rates for such stones range from 73.3 to 83.3% with many requiring only one or two treatments despite stone size being well above 2 cm [86–88]. For larger and staghorn stones in children, preoperative stent or nephrostomy decreases SWL complications [6, 7, 86]. Although there is no official recommendation, low energy levels and fewer shocks should be used in children [45].

## Follow-up after shock-wave lithotripsy and managing failure

There is no consensus on follow-up imaging after SWL. Obtaining plain abdominal radiography (i.e. KUB) 1–4 weeks after SWL is reasonable to evaluate success. Stone fragments less than or equal to 4–5 mm can be observed if asymptomatic but may lead to future colic events or serve as a nidus for stone recurrence [8, 89]. In one study evaluating the long-term outcome of stone fragments less than or equal to 4 mm after SWL, 21.4% of residual fragments led to stone recurrence and retreatment in the 5 years of follow-up [90]. Presence of fragments greater than or equal to 4 mm that persist 3 months after SWL were a significant independent predictor of clinically significant events in another study [89].

Repeat SWL can be considered based on initial treatment success or failure. There is no consensus on the timing between repeat sessions of SWL for renal stones; however, European Association of Urology guidelines approve of within 1 day for ureteral stones [8]. When repeat SWL was compared to surveillance in a RCT on persistent renal stone fragments after initial SWL, 3 month follow-up showed significant decrease in residual debris in those who were retreated [91]. Many studies evaluating SWL outcomes document SWL failure as being after three sessions [36, 39, 92]. In a RCT on SWL versus PCNL, renal scarring was assessed using $^{99m}$Tc-labeled dimercaptosuccinic acid (DMSA) scintigraphy; 16% of the patients in the SWL group had scarring, all of whom had three SWL sessions and only one of which became stone-free [92]. Studies have also demonstrated decreasing success rates (i.e. diminishing returns) with each successive SWL treatment for both renal and ureteral stones [41, 93]. American Urological Association guidelines recommend offering endoscopic therapy as the next treatment option in those who fail a single SWL [6, 7].

## Conclusions

In 2017, SWL has a clear role in the surgical management of renal stones and remains the least invasive treatment option. The decision for SWL versus other treatments is affected by many variables outlined in this chapter. Future directions may be aimed at improving SWL success rates on newer-generation machines as well as novel techniques to overcome barriers to stone fragmentation.

## Introduction

Over the past decade, the number of patients with upper urinary tract calculi undergoing shock-wave lithotripsy (SWL) has decreased across the globe [1, 2]. This trend is a reflection of a number of factors including improvements and widespread availability of flexible ureteroscopes and intracorporeal lithotripsy devices, as well as the perception that SWL efficacy with the newest generation of lithotripters is less than with the endourological alternatives. Despite the expanding role in particular for flexible ureteroscopy in the management of upper ureteral calculi, SWL remains a popular therapeutic option for patients [3–5].

Contemporary experience highlights the importance of proper patient selection in achieving successful outcomes with SWL. Technique and the employment of adjunctive measures have also been shown to promote stone fragmentation and stone clearance. In this chapter, the current indications, clinical outcomes, and techniques to enhance efficacy of SWL in the management of ureteral stones are reviewed.

## Current indications for shock-wave lithotripsy of ureteral stones

Current clinical practice guidelines have emphasized the importance of proper patient selection when considering SWL for an individual patient with a ureteral stone. Stone factors such as size, location, multiplicity, radiopacity, composition (if known), as well as patient factors including body habitus, patient body mass index (BMI), and collecting system anatomy may be useful clues predicting success. Surrogate markers can also be used to help determine whether SWL is worth considering for an individual patient. Hounsfield unit (HU) measurements on computed tomography (CT) scanning can reflect stone hardness and the likelihood of successful fragmentation, which maybe especially useful if stone composition is unknown. Skin-to-stone distance (SSD) determined by CT scan provides additional information on the potential impact of patient body habitus on treatment success.

The 2016 American Urological Association (AUA)/ Endourological Society surgical management of stone guideline emphasized the usefulness of CT in optimizing individual patient treatment while remaining cognizant of radiation exposure risk [6]. CT has the highest accuracy in determining stone size and location and can provide HU and SSD information.

Stone burden and individual stone size have well-known effects on SWL outcomes of renal stones. In a multivariate analysis, renal stones <15 mm in size were associated with a 1.94 times greater chance of clearance post-SWL than stones larger [7]. As for renal calculi, different cutoffs, ranging from 8 to 12 mm, have been suggested for ureteral calculi [8–10]. Every research group evaluating the influence of variables on success after SWL retained stone size or a surrogate thereof such as stone diameter or surface area as an independent predictor of success [11–17]. Overall, stones larger than 1 cm are considered to have a lower success rate with SWL.

Obesity and diabetes have been widely recognized as important risk factors for urinary stone disease with an increasing influence on prevalence [18]. The effect of patient BMI was first highlighted by Pareek et al. who demonstrated that failure of SWL for renal and proximal ureteral stones was associated with an average BMI of 30.8 $kg/m^2$ [19]. The effect of SSD as a surrogate for BMI has been clearly demonstrated in a number of studies.

For ureteral stones, however, the literature does not unanimously report a negative impact of a higher SSD [20–22]. Initially, Wiesenthal et al. reported a SSD <11 cm to be a significant predictor of success for renal and ureteral calculi [20]. In a multivariate analysis on the same population, however, evaluating renal and ureteral calculi separately and using SSD as a continuous variable, SSD was no longer a predictor of success for ureteral calculi [12]. Although initially, a 10 cm cutoff for SSD was proposed above which SWL was less successful [19], more recent reports demonstrate a cutoff of 11–12 cm [20, 22, 23]. Whether this is a reflection of the specific geometry of different lithotripters used is unclear. Needless to say, an understanding of the specifications of one's particular lithotripter is important when considering factors that might affect treatment efficacy.

Stone composition has a well-documented impact on SWL efficacy. Ringdén and Tiselius described stone hardness as a stone's resistance to shock-wave therapy, based on the results of SWL of 114 stones treated *in vivo* [24]. Uric acid/urate, struvite mixed-infection stones, and calcium oxalate dihydrate stones are most responsive to SWL, followed by, in order of increasing hardness, hydroxyapatite, carbonate apatite, calcium oxalate monohydrate, brushite, and cystine stones [24]. This was similarly identified by Parks and colleagues [25]. Among patients with suspected or known cystine or uric acid stones, SWL is typically not the preferred modality, as they are often poorly visualized on fluoroscopy, making stone targeting problematic. Even if ultrasound targeting is available on the lithotripsy machine, identifying a ureteral stone can be challenging. Cystine stones are typically resistant to SWL fragmentation due to their organic nature. The AUA/Endourology Society guideline based on expert opinion recommends ureteroscopy as the first-line therapy for patients with ureteral stones and these specific stone compositions requiring treatment [6]. Cystine and calcium oxalate monohydrate stones, in addition to being hard, also tend to break into relatively large pieces that may be difficult to clear from the collecting system [26, 27]. For those patients with the more difficult to fragment stone compositions, SWL should be reserved only for small volume stone burdens [28]. Matrix calculi although relatively soft being composed of predominantly organic matter, also respond poorly to SWL fragmentation efforts [29].

When stone composition is not known, noncontrast CT imaging with measurement of the stone HU value can be a useful proxy. A number of studies have evaluated different HU cutpoints ranging from greater than 750 to 1000 as predictors of SWL failure for ureteral stones [19–22, 30, 31]. In summarizing the current literature, McClain et al. suggest using a liberal estimate of 1000 HU [32], with higher values associated with lower stone fragmentation rates. It is important to realize that most of these papers included both renal and ureteral stones and that these cutoffs may therefore not be completely applicable to ureteral stones.

Williams et al. demonstrated that with an increasing collimation width, an increasing underestimation of the HU has to be taken into account due to the volume averaging effect of CT imaging [33]. As most stone protocol CTs apply a 5 mm collimation width, the HU measurements of small stones are most likely an underestimation of the actual stone density [34]. This may explain why the calculated cutoff HU for SWL success is lower than the generally applied 1000 HU in datasets including a large proportion of ureteral stones.

Results in the literature are conflicting on whether hydronephrosis has a negative effect on outcomes of SWL for ureteral calculi [13, 16, 35–37]. Recent research indicates that approximately 89% of patients with symptomatic ureteral stones have at least a mild degree of hydronephrosis [38]. The only variable directly correlated with the degree of hydronephrosis was stone size [38]. The degree of obstruction did not appear to have any influence on success rates of SWL for solitary distal ureteral stones in a report by Demirbas et al. [35]. In a cohort of nearly 700 ureteral stones treated by SWL, obstruction appeared to have a negative effect on success, but did not reach statistical significance in a multivariate analysis (odd ratio 1.93, 95% confidence interval [CI] 0.99–3.77, $P = 0.053$) [16]. Although Seitz and associates identified a success rate of 86.7% for nonobstructing and a 70.5% success rate for obstructing proximal ureteral stones, similarly they could not demonstrate this difference to be statistically significant [36]. El-Assmy et al. came to the same conclusion, but did identify patients with hydronephrosis to need more SWL sessions to reach stone-free status and to evacuate fragments after SWL [37]. In an effort to develop a clinical nomogram to predict outcomes after SWL, Kim and colleagues identified hydronephrosis as an independent predictor of failure in a cohort of over 3000 patients [13]. Ureteral wall thickness may be a surrogate for impaction and hydronephrosis and has been demonstrated to decrease success rates of SWL for proximal ureteral calculi [39].

Many variables have been shown to influence stone fragmentation and clearance of fragments after SWL. Although anatomic abnormalities of the urinary tract may not directly influence fragmentation, they may hinder clearance of fragments [40].

Contraindications to SWL of ureteral stones are similar to those for renal stones. Pregnancy remains an absolute contraindication due to the uncertain effects on the fetus [41]. Untreated urinary tract infection (UTI), unrelieved urinary tract obstruction, uncorrected bleeding diatheses, and adjacent arterial aneurysm are other well-described contraindications [42–44].

## Outcomes

### Proximal, mid, and distal ureteral locations

Several large series identify the difference in success rates of SWL for ureteral calculi in different locations: 70–97% for proximal stones, 58–97.8% for mid-ureteral stones, and 54–97.9% for distal ureteral calculi (Table 61.1) [9, 11, 16, 17, 45–47].

Contemporary series of SWL and ureteroscopy for patients with ureteral calculi describe reasonably high stone-free rates (SFR) with both modalities. The ability to achieve a stone-free state with a single procedure was assessed in the 2007 European Association of Urology (EAU)/AUA Guideline for the management of ureteral calculi [48]. For stones in the proximal, middle, and distal ureter the number of ureteroscopy procedures necessary to achieve stone clearance was 1.01, 1.00, and 1.00 respectively. For SWL, the review documented 1.34, 1.29, and 1.26 procedures required for proximal, middle, and distal stones respectively. The 2016 AUA/Endourology Society guideline panel's meta-analysis identified superior SFR overall for ureteroscopy over SWL for stones regardless of size and location (90% for ureteroscopy vs. 72% for SWL) [6]. A subanalysis of upper ureteral stones >10 mm in size determined that SFR was comparable (74% for SWL vs. 79% for ureteroscopy). For mid and distal ureteral stones >10 mm, the evidence favored ureteroscopy over SWL (82.5 vs. 67% and 92 vs. 71% respectively). The greater disparity in SFR for mid and distal ureteral stones between ureteroscopy and SWL lead the AUA/Endourology Society guideline panel to give a strong recommendation in favor of ureteroscopy as the first-line therapy for patients with stones in these specific locations. The updated 2016 EAU guideline recommendations are slightly different and suggest SWL as first-choice for proximal stones <10 mm and no preference of SWL or ureteroscopy for distal stones <10 mm [49].

### Pediatric stones

The 2016 AUA/Endourological Society guideline on urinary stone management reported the results of a meta-analysis indicating SWL and ureteroscopy have similar efficacy for stones of varying size in pediatric patients. Pooled success rates were 87 and 95% respectively for stones <10 mm and 73 and 78% for stones >10 mm [6]. These results are confirmed in a large retrospective cohort of pediatric stones, including 1345 ureteral calculi [50]. Although patients needed fewer auxiliary treatments after ureteroscopy (13.6 vs. 18.8%), the authors reported a higher readmission and emergency room visit rates when compared to patients treated with SWL (7.9 vs. 4.9%) [50].

### Treatment safety

SWL continues to demonstrate lower treatment related morbidity compared to ureteroscopy with a Cochrane review noting a significantly lower complication rate for SWL (relative risk 0.54, 95% CI 0.33–0.88, $P = 0.01$) [51]. The 2016 AUA/Endourology guideline found no differences in the rates of UTI, sepsis, ureteral stricture,

or avulsion between SWL and ureteroscopy; ureteral perforation occurred more commonly during ureteroscopy [6].

Based on a systematic review evaluating the use of antiplatelet/anticoagulation therapy during SWL of renal and ureteral stones, Schnabel and colleagues highlight that bleeding risk of SWL for patients on acetylsalicylic acid has to be weighed against the risk of a cardiovascular event with discontinuation [52]. Whether SWL of ureteral stones is less likely to be associated with bleeding complications for patients who remain on acetylsalicylic acid is unknown. In patients with uncorrected bleeding diatheses or who are unable to discontinue anticoagulation/antiplatelet agents, SWL should still be considered potentially hazardous due to bleeding risks. Ureteroscopy is the recommended treatment modality in these patients [6].

According to the 2016 AUA/Endourological Society guidelines, SWL does not require pretreatment antimicrobial prophylaxis in the absence of a UTI [6].

As demonstrated by a meta-analysis, antibiotic prophylaxis prior to SWL in low-risk patients does not confer a lower risk of post-SWL UTI [53]. The EAU guidelines suggest that in patients with a higher risk of bacterial burden due to presence of an indwelling catheter, stent, nephrostomy tube, or infectious stones, prophylactic antibiotics may be warranted [49].

The safety of SWL for ureteral calculi in children is well established with multiple reports of low complication rates [54–56].

Polat and colleagues demonstrated almost half of the patients >65 years treated with SWL for ureteral or renal calculi to have at least one medical comorbidity [57]. They observed a low major complication ratio (2.1% steinstrasse, 1.2% hematomas, and 0.4% pyelonephritis), concluding SWL to be safe in the elderly population [57].

Theoretical concerns exist about the effects of SWL on the reproductive organs. Among females, the ovaries may be located in the blast path during treatment of distal ureteral calculi, whereas in males, the vas deferens, seminal vesicles, and prostate may be affected. Although *in vitro* studies suggest spermatozoa are vulnerable to shock-wave energy, animal studies could not uniformly corroborate these results [58]. Results from clinical trials indicate that there may be a transient decrease in sperm motility and sperm count which resolves by 3 months after the treatment [58].

Although concerns about ovarian effects exist, a decrease in fertility has not been demonstrated in female human subjects who underwent SWL for distal ureteral calculi [59, 60]. SWL for distal ureteral stones should be considered a safe treatment not influencing fertility in patients of reproductive age in either sex.

## Strategies to enhance efficacy

In addition to optimal patient selection for SWL, there are many technical factors that can influence treatment success. It is important to emphasize that technical factors should be optimized at the first SWL attempt. Pace et al. demonstrated that repeat SWL treatments for ureteral calculi unresponsive after the first attempt procure only a limited increase in SFR [46]. The cumulative SFR increased from 68 to 76% with one additional treatment and to 77% with a third treatment [46].

### Imaging guidance

Correct targeting is imperative for achieving SWL success. Although ultrasound guidance can be used for SWL treatment of renal stones, this imaging modality is more challenging for ureteral stones. Fluoroscopic guidance is more commonly employed. For faintly radiopaque or radiolucent stones, a bolus of intravenous contrast can be administered or retrograde ureteropyelogram performed, allowing targeting of the filling defect [61].

### Patient positioning

In an *in vitro* SWL study, Olvera-Posada et al. demonstrated that the interposition of bony structures in the shock-wave path had a detrimental effect on shock-wave efficacy [62]. As ureteral stones can overlie the transverse process of lumbar vertebrae, this should be taken into account during patient positioning.

In order to avoid interposition of bony structures in the shock-wave path, Hara and colleagues demonstrated that rotating the patient toward the therapy head increased the success rate significantly for mid- and distal ureteral calculi (from 83.9 to 95% and from 89.1 to 98.0% respectively) and a significant decrease in number of SWL sessions for proximal stones [63].

Kose and Demirbas reported higher fragmentation rates with a modified prone position for distal ureteral stones where the obliquely oriented therapy head is positioned on the opposite side of the stone compared to a conventional prone approach (97.5 vs. 89.9% respectively, $P = 0.015$) [64]. Distal stones can also be targeted in a supine position with the shock-wave energy directed through the greater sciatic foramen or supine with the therapy head positioned in an over-patient position (Figure 61.1). The main drawback of a supine approach is the interposition of bony structures, whereas in a prone position bowel gas may attenuate the shock waves and the SSD distance may be higher. A meta-analysis demonstrated a success rate of 89.6% for the supine position

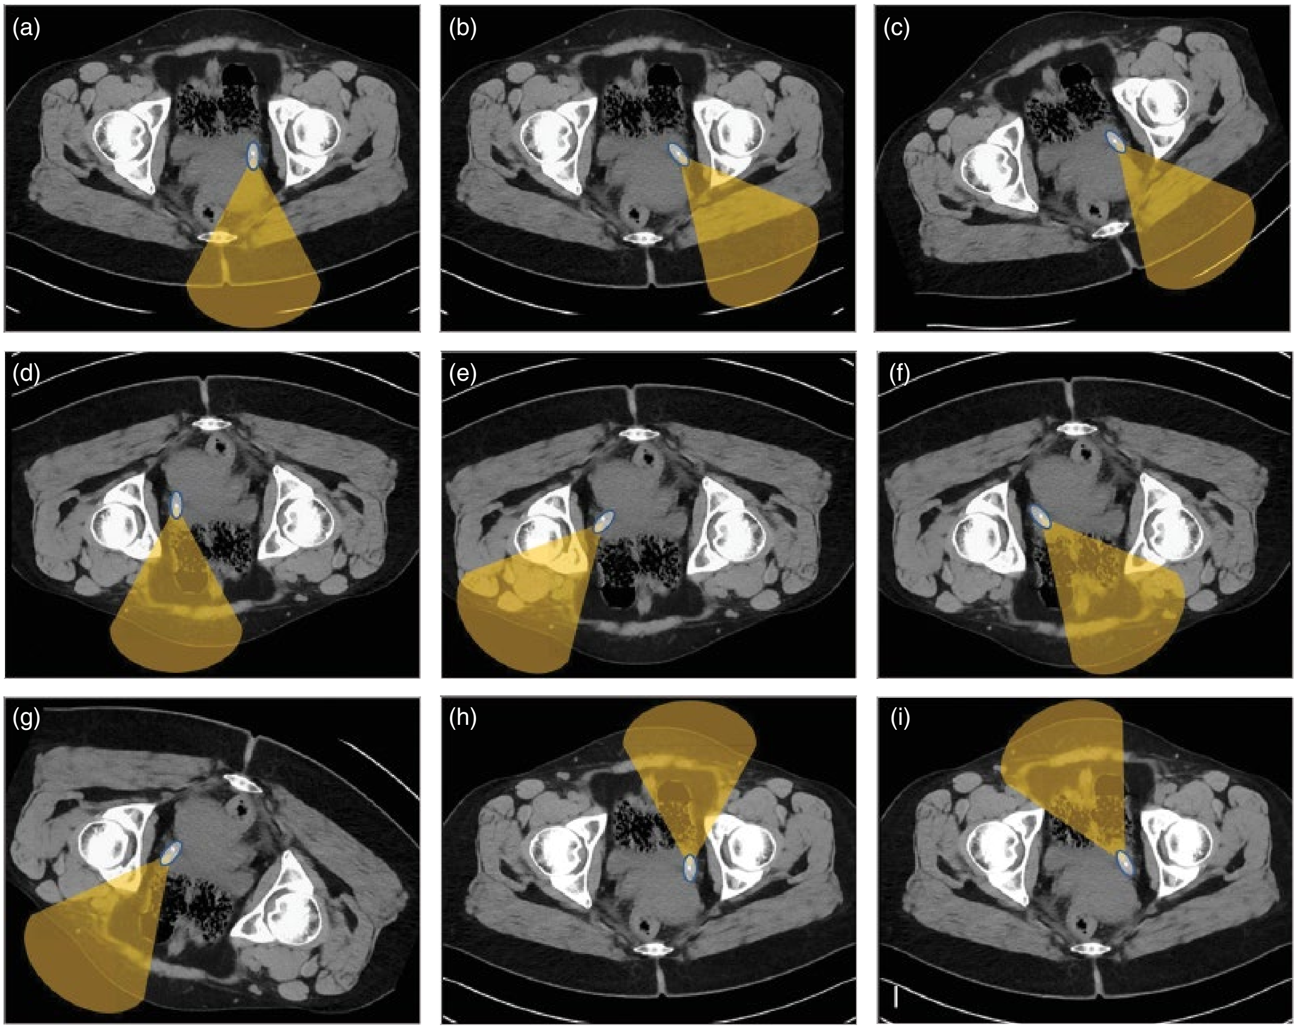

**Figure 61.1** Different possible positions for targeting a distal ureteral stone. (a) Supine vertical therapy head, (b) supine oblique therapy head, (c) modified supine, oblique therapy head, (d) prone, vertical therapy head, (e) prone, oblique therapy head, from ipsilateral side, (f) prone, oblique therapy head from contralateral side, (g) modified prone, oblique therapy head from ipsilateral side, (h) supine, over-patient vertical therapy head, and (i) prone, over-patient oblique therapy head, from contralateral side. *Source:* EDAP-TMS France. Reproduced with permission of EDAP-TMS France.

versus 72.7% for the prone position [65]. Phipps et al. achieved a higher success rate with patients in a supine position using a transgluteal shock-wave path but cautioned that success is operator-dependent and having the sciatic nerve in the blast path may be painful for the patient [66].

## Respiratory motion

Recent data suggests that ureteral stones are considerably less influenced by respiratory motion than renal stones, with renal stones moving over a range of 7.7 ± 2.9 mm and ureteral stones over a range of 3.6 ± 2.1 mm [67]. Abdominal compression belts or plates are therefore of limited benefit for treatment of ureteral calculi.

## Coupling

*In vitro* and clinical research has demonstrated that air bubbles caught in the coupling gel of the therapy head have a detrimental effect on SWL efficacy [68, 69]. Tailly et al. demonstrated that a camera incorporated in the therapy head can help evaluate the coupling area, creating awareness of the presence of air bubbles and prompting manual removal [70].

## Diuresis

Azm and Higazy were the first to report a beneficial effect of forced diuresis on SWL outcomes especially for distal ureteric stones [71]. Whereas Zomorrodi and colleagues achieved similar results [72], Tiselius and colleagues demonstrated no difference in SWL success with or without forced diuresis, but suggest diuresis is still worthwhile post-SWL [73, 74].

### Medical expulsive therapy

Medical expulsive therapy (MET) as the initial management option for ureteral calculi is controversial as a recent large randomized controlled trial (RCT) contradicted a previously published meta-analysis [75, 76]. Skolarikos and colleagues performed a systematic review on the use of MET after SWL to improve clearance of fragments and pooled the results of 26 trials [77]. Their results endorse the use of MET, mainly alpha-blockers, to improve clearance rate and clearance time after SWL [77]. Eryildirim and associates additionally reported that MET post-SWL for ureteral calculi could increase patients' quality of life [78].

### Stenting

According to the most recent AUA/Endourological Society stone guidelines, routine stenting should not be performed in patients undergoing SWL [79]. This recommendation is based on a meta-analysis published in 2011 that included eight studies and 876 patients [80]. Although no difference was noted for success rate after SWL, the review did show a benefit of reducing the steinstrasse rate with stenting [80]. This result was largely influenced by one study including 400 patients with renal stones measuring 1.5–3.5 cm [81]. Several studies have even shown a significantly reduced treatment success after SWL for ureteral stones in stented patients [16, 45, 46, 82].

### Treatment timing

Pooling data from seven studies, Picozzi et al. performed a meta-analysis on the differences between emergent and delayed SWL for ureteric stones [83]. Out of the three included RCTs, only Tombal et al. demonstrated that immediate SWL significantly improved SFR for proximal ureteral stones as determined at 48 hours after treatment [84–86]. A shorter hospital stay as well as the need for fewer auxiliary procedures are some of the reported benefits of emergent SWL [85, 86]. Although underpowered, a recent RCT corroborated these findings with a success rate of 93.8% for immediate versus 80% for delayed SWL [87]. The pathophysiology accountable for this phenomenon is hypothesized to be a lack of edema in the early stages of ureteric colic, which may allow an expansion chamber to form, enhancing fragmentation [83, 88].

## Treatment protocol

### Voltage ramping

Zhou et al. demonstrated that a stepwise increase of voltage procures the best comminution results in *in vitro* and animal experiments [89, 90]. This phenomenon was verified in a clinical RCT including 50 patients with upper tract urinary calculi up to 2 cm, including 20 ureteral calculi [91]. The only RCT on voltage ramping for ureteral calculi did not demonstrate an advantage over fixed voltage SWL [92].

During SWL treatment of proximal ureteral calculi, renal parenchyma may be in the blast path of the shock wave. As several authors have reported voltage ramping to decrease the chance of renal hematoma, this should be taken into account when treating stones in this location [82, 93]. When SWL is not performed under general anesthesia or conscious sedation, Berwin et al. suggested that voltage ramping is additionally of importance for pain tolerance during the treatment [94]. When treating a ureteral stone under general or conscious sedation, without having any renal parenchyma in the blast path, voltage ramping seems to be of minimal benefit.

### Pretreatment and pause

There is extensive *in vitro* and *in vivo* research experience endorsing a low-voltage pretreatment to improve stone fragmentation and decrease damage to renal parenchyma [95–98]. The most recent report would indicate that 300 shocks at low voltage without a pause has the best renoprotective effect while improving fragmentation [98]. Although clinical data is lacking for ureteral stones, pretreatment can be taken into account when renal parenchyma is in the blast path when treating upper ureteral calculi.

### Shock-wave rate

The superiority of a slower shock-wave rate on treatment efficacy has been demonstrated both *in vitro* and *in vivo*. Greenstein and Matzkin initially identified a 1 Hz shock-wave rate to be most efficient for stone comminution in an *in vitro* setting [99]. Paterson et al. corroborated these results in an *in vivo* porcine model, demonstrating that a 0.5 Hz shock-wave rate produced better stone comminution than a frequency of 2 Hz [100]. Utilizing the same *in vivo* model, Connors and colleagues later demonstrated that a shock-wave rate of 1 Hz had a smaller negative effect on glomerular filtration rate(GFR) and renal plasma flow when compared to a 2 Hz regimen, without applying a pretreatment, treatment pause, or voltage ramping [101].

A meta-analysis including 2144 patients from 13 RCTs demonstrated slower shock-wave rates of 1–1.5 Hz to have a superior success rate as compared to 2 Hz, without a significant difference in complication rate [102]. Pooled data analysis, however, could only identify this beneficial effect for stones larger than 10 mm, whereas the shock-wave rate did not seem to influence the success rate for smaller stones [102]. Although this meta-analysis included treatment of 738 ureteral stones from seven studies, of which 339 were treated at a low shock-wave rate, 247 at a intermediate shock-wave rate, and 152 at a high shock-wave rate, a subgroup analysis was not performed [103]. Several groups have focused on differences in shock-wave rate effect on ureteral stones alone [104–106]. Whereas Honey and colleagues demonstrated the benefit of a slow shock-wave rate for proximal ureteral stones, Anglada-Curado et al. have shown a slow shock-wave rate to be superior in a cohort of distal ureteral stones. In contrast to the results of these two trials, Nguyen et al. found a shock-wave rate of 1.5 Hz to result in a higher success rate when compared to 1 Hz [104]. It should be noted that most stones included in this study were smaller than 10 mm in diameter and that analysis could not demonstrate a difference in effect for distal stones [104]. See Box 61.1.

**Box 61.1 Shock-wave lithotripsy of ureteral stones: treatment protocol suggestions.**

- For stones >10 mm, use a shock-wave rate of 60–90 shocks/minute (1–1.5 Hz)
- Low-voltage pretreatment with approximately 300 shocks for proximal ureteral stones (especially if renal parenchyma is in the blast path of the shock wave)
- A treatment pause has no proven benefit
- In treatment of mid-ureteral to distal stones under conscious sedation or general anesthesia, voltage ramping may be omitted.

## Summary

Claims that SWL no longer has a role in the management of upper urinary tract calculi are unfounded. Urologists should be selective when choosing SWL, but in the properly identified patient with a ureteral stone, SWL remains a beneficial therapeutic option with low morbidity and high patient acceptance.

In comparison with percutaneous nephrolithotomy and ureteroscopy, data on extracorporeal shock-wave lithotripsy (ESWL) show that fewer complications occur for this procedure [1, 2]. To make differentiation easier, this chapter is divided into three parts: side effects, complications (which need medical intervention), and long-term effects. Other complications (cardiovascular and gastrointestinal) are rare.

## Side effects

Shock-wave lithotripsy (SWL) arguably has been the safest available surgical modality for stone removal in the decades since its introduction into clinical use in the 1980s. As with other stone removal modalities there are side effects, which cannot be counted as complications and are therefore listed separately.

### Hematuria

Hematuria following SWL is one of the most common findings and usually resolves within a few hours. The effect in vessels can be differentiated by measuring α2-macroglobulin enhancement found immediately after and 1 day following SWL [3–5]. Changes in specific hemostatic biomarkers in venous blood samples, at least during the first 4 hours post-SWL, underline this side effect [6].

### Detoriation of renal function

Several blood and urine markers can indicate possible renal injury shortly after SWL. Glomerular filtration rate, β2-microglobulin measures in serum and urine, as well as serum creatinine measures after SWL treatment suggest that ESWL does not have any long-term effect on the glomerular filtration rate; however, it leads to transient proximal tubular dysfunction for up to 7–9 days. Early retreatment, at least with piezoelectric sources, does not enhance several marker measures, in particular proteinuria. [5, 7]. Transient proteinuria, however, might last for up to 3 months until a return to baseline [8].

In an animal model it has been shown that small kidneys tend to show more tissue damage when exposed to SWL [9]. Looking at the smaller kidneys of children treated with SWL by analyzing urinary enzyme levels, the regeneration time of tubular function in children appears to be longer than for adults (14 versus 7 days) [10].

### Renal colic (manageable conservatively)

The probability of suffering from renal colic during fragments passing down the ureter appears to be about 2–4% [11]. However, it does depend in several predisposing factors, such as stone size. Most of these events can be managed by oral medication and should be counted as expected side effects. However, colic, including the development of steinstrasse, that requires intervention or emergency room visits is a complication and discussed later in the chapter.

## Complications

### Steinstrasse

Steinstrasse is an accumulation of stone fragments or stone gravel in the ureter, which does not pass within a reasonable period of time and interferes with the passage

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.
© 2019 John Wiley & Sons Ltd. Published 2019 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/smith/textbookofendourology

of urine [12, 13]. Steinstrasse occurs in 4–7% of cases following SWL [14–16], and the major risk factor for the formation of steinstrasse is stone size [15].

Although Coptcoat's classification of steinstrasse exists (Type I, fragments <2 mm in diameter; Type II, leading fragment 4–5 mm tailed by 2 mm particles; and Type III, consisting of large fragments), it is not widely used [13].

Clinically, steinstrasse can be symptomless or present with combinations of flank pain, fever, nausea and vomiting, or bladder irritation. Steinstrasse can cause obstruction of the ureter, which can be silent in up to 23% of cases [15] and can lead to failure of the function of the kidney [17]. In solitary kidneys anuria occurs in 5% of cases [15]. The insertion of a ureteral stent before ESWL might prevent formation of steinstrasse [18].

When steinstrasse is not symptomatic, conservative treatment is an initial option, depending on patient preference and the willingness to comply with a close surveillance schedule. Medical expulsive therapy might significantly increase stone expulsion rate and decrease need for endoscopic intervention [19, 20]. The patient should be informed about the controversial literature on medical expulsive therapy using alpha-blockers as well as its off-label use [21].

In cases where spontaneous passage is unlikely and interventional treatment becomes necessary, several options apply: SWL is one of the options in asymptomatic or symptomatic cases with no evidence of urinary tract infection, when large fragments of stones are presented [22]. There is an 80% chance of clearance of the steinstrasse [14].

Ureteroscopy is more effective but more invasive than SWL in treating steinstrasse (73–90%) [22–24].

Placement of a percutaneous nephrostomy tube is indicated in cases of symptomatic ureteric obstruction with or without urinary tract infection, and it is effective in 83% cases [14].

## Colic needing intervention

When conservative treatment of renal colic fails intervention therapy is indicated. Choosing the treatment method in cases when signs of urinary tract infection are not presented is based on size, location, and X-ray density of the blocking stone fragment. As in the treatment of ureteric stones, SWL or ureteroscopy is indicated [25]. Insertion of double-J stent or percutaneous nephrostomy tube is indicated in cases complicated by urinary tract infection.

## Infectious complications

Infectious complications of SWL are caused by renal trauma and vascular damage during SWL, facilitating bacteria to migrate into the blood vessels. Duvdevani et al. [26] showed in a prospective evaluation of 15 000 SWL treatments that bacteriuria after SWL occurred in 5.1% in spite of preoperative sterile urine. The most common pathogens were *Escherichia coli* (35.1%), *Pseudomonas aeruginosa* (16%), *Klebsiella pneumoniae* (12.8%), *Proteus mirabilis* (11.7%), *Enterococcus faecalis* (8.5%), and *Enterobacter cloacae* (4.3%). The risk of fever >38 °C, however, was only 1.4%. The probability of fever and bacteriuria is increased when an untreated or symptomatic urinary tract infection is present, a double-J catheter or nephrostomy tube is inserted, or when treating struvite stones (17.7 vs. 2.1%, $P < 0.05$) [27].

No standard antibiotic prophylaxis before SWL is recommended. However, in view of the abovementioned risk factors prophylaxis is recommended in the case of internal stent placement ahead of anticipated treatments and in the presence of increased bacterial burden (e.g. indwelling catheter, nephrostomy tube, or infectious stones) [28–30].

## Hematoma

On using computerized tomography routinely after SWL, perinephric soft-tissue stranding and fascial thickening were seen in up to70%. In addition, hematomas may be detected in 15%, being big in 2% [31], and using magnetic resonance subcapsular or perinephric fluid can be seen in up to 26% of cases [32]. Routine ultrasound after SWL detects hematomas in approximately 4%. The probability of developing a hematoma increases significantly with patient age. However, most of these changes remain asymptomatic [33]. The effect might depend on the lithotripter being used [34, 35].

Potential risk factors for hematoma development are any kind of coagulopathy including that induced by medication, hypertension, diabetes mellitus, coronary artery disease, obesity, and obviously age [35, 36].

In most cases hematomas are, or become, asymptomatic and might resolve within 2 years. Krishnamurthi and Streem followed 19 patients with post-SWL hematomas found on routine ultrasound for up to 61 months (mean 19.6 months). They showed a complete resolution of the hematoma in 85.7%, a significant reduction in 9.5%, and just one patient remained unchanged. There was no new onset or aggravation of pre-existing hypertension [37].

Stepwise voltage ramping can reduce the risk of developing hematomas (odds ratio 0.39, 95% confidence interval 0.19–0.80; $P = 0.01$) [38] in addition to considering the above mentioned risk factors [38].

## Cardiovascular complications

The incidence of cardiac of dysrhythmias varies from between 11 and 59% during ungated SWL [39, 40].

No correlation was mentioned between evidence of dysrythmias and type of lithotripter, number of shock waves, patient age, stone size and location, and type of anesthesia [39].

The incidence of morbid cardiac events or biochemical myocardial injury is extremely rare [41, 42].

Patients with a pacemaker can be treated with SWL, provided that appropriate technical precautions are taken; patients with implanted cardioverter defibrillators must be managed with special care (firing mode temporarily reprogrammed during SWL treatment). However, this might not be necessary with new-generation lithotripters [43, 44].

The SWL treatment in patients with aortic aneurysm is controversial. There are reports of rupture of aortic aneurysm due to SWL treatment [45, 46] and reports of safe treatment [47]. According to Tse et al.'s review of 18 SWL treatments in patients with aortic aneurysm, there is currently no high-level evidence to suggest that SWL in the presence of arterial aneurysm is unsafe [48]. However, an aneuryma in the vicinity of the stone and focal zone of SWL remain a contraindication for SWL treatment [36].

### Gastrointestinal complications related to SWL treatment

Gastrointestinal damage has been reported as a rare potential complication of SWL. The actual incidence is unknown. In a review, Maker and Layke reported 62 cases of gastrointestinal damage of 3423 patients (1.81%); only 28 (0.82%) were symptomatic, including nine bowel perforations [49]. The etiology of gastrointestinal damage is unknown; however, the majority of cases were reported in patients treated in prone position and with a higher number of applied shock waves [49].

Gastric and duodenal erosions recorded by pre- and post-ESWL endoscopy was found in 80% of the patients [50]. Ureterocolic fistula due to SWL [51] and dehiscence of gastrointestinal anastomosis [52] are reported, too.

Hepatic hematoma and spleen hematoma are rare complications of SWL. There were only 13 cases reported of hepatic [53] and seven of spleen hematomas [54, 55]. Due to the situation that the liver and spleen are intraperitoneal organs that lack a tough fascia, the need of surgical intervention is higher than in patients suffering post-SWL renal hematomas.

Elevation of serum amylase and lipase is presented in patients with acute pancreatic trauma. Only Kirkali et al. found significant elevation (but within physiological levels) of amylase and lipase in patients who underwent SWL of upper tract stones compared to patients treated for lower ureter stone [56]. There was no change recorded when treatment on newer generations of lithotripters was performed [57–59].

Case studies describe formation of a pancreatic abscess following SWL treatment for right renal stone [60] and pancreatitis after treatment in right and left kidney [61–63]. However, there is only a very limited number of cases described worldwide. A systematic review focusing on chronic calcified pancreatitis treated with SWL included 17 out of 31 studies and did not show any negative sequelae of SWL, like new onset of abscesses, although SWL was focused on pancreatic tissue [64].

## Long-term effects

### Diabetes mellitus

Looking at long-term effects, 19 years after SWL treatment Krambeck et al. performed a questionnaire-based evaluation of their patients treated in 1985 ($n = 578$, reponse rate 58.9%) and found an association of SWL treatment and the development not only of hypertension but also diabetes mellitus compared to a cohort of conservatively treated patients with nephrolithiasis [65]. This reflects the technology used 1985, however, and might differ from later research. In 2015 a systematic review on new-onset DM was performed including three case-control and two cohort studies out of 55 studies of a comprehensive search; a statistical association of SWL with new-onset of DM could not be found in the overall analysis [66].

### Effect on reproduction organs and pregnancy

Animal studies could not show any detrimental effect on sperm morphology [67]. A retrospective study following 84 women in reproductive age after SWL of distal ureteral stones suggests that SWL does not affect female fertility or lead to increased teratogenic risk [68]. SWL is contraindicated during pregnancy. Animal studies in mice showed decreasing number of surviving fetuses in proportion to increasing number of shock waves applied on the fetus, in particular during late pregnancy [69]. Shock waves targeted into the fetus of rabbits where fatal as well for the fetus in another study; however, fetuses outside the focal zone were vital and free of lesions; embryotoxic or teratogenic sequalae could not be shown in this study [70]. Case reports of successful delivery of healthy babies even when inadvertently treated with SWL because of distal ureteral [71] or renal [72] stones underline the importance of further research.

### Hypertension

Results of retrospective studies suggest an increase on developing diastolic hypertension following SWL

[73, 74], which is in contrast to prospective studies. Prospective observational studies were published in 1992 including 68 patients followed for 36 months after SWL treatment using a modified Dornier HM3 lithotripter; compared to first measurements 15 days prior to SWL-treatment no significant increase of mean diastolic blood pressure was seen [75]. Jewett et al. randomized patients with asymptomatic calyceal stones smaller than 2 cm to receive immediate SWL versus observation and followed them for a longer period (mean 22 months); they found no difference in new onset of hypertension. In contrast they demonstrated a decrease of mean diastolic blood pressure in the treatment group ($P < 0.03$); the results were independent of patient's age [76] and the SWL energy source used was electromagnetic. In a similar study Elves et al. randomized patients with stones up to 15 mm and followed 200 of them for at least 1 year, and a mean of 2.2 years. They found no evidence that SWL treatment causes changes in blood pressure; they used two different lithotripters [77].

Another prospective study used 24 hour ambulatory blood pressure monitoring; they studied 60 kidney stone patients and 30 patients with distal ureteral stones, all treated with SWL (Dornier HM4) and another group of patients with ureteral stones treated with ureteroscopy. After 1 year of follow-up they found a significant decrease in blood pressure values in the patient group treated for kidney stones, which was related to the power and number of shock waves. The authors speculated that these changes possibly were caused by alterations in intrarenal metabolism [78].

According to a meta-analysis including 11 studies, published by Yu et al., no statistical significance was detected between SWL and new-onset hypertension (relative risk 1.06, 95% confidence interval 0.83–1.35) [79].

## Introduction

Technologic advances in the surgical and medical therapy of urinary stone disease over the last three decades have allowed urologists to offer numerous treatment options for symptomatic and asymptomatic upper tract urinary stones. As with any disease, one of the options to be entertained is that of active surveillance/observation for asymptomatic stone disease. Observation is a reasonable approach and an often desired treatment option by the patient to limit costly and potentially painful interventions. However, before choosing observation physician and patients alike must be aware of the potential ramifications of leaving upper tract stones untreated in a variety of different clinical scenarios. In order to assist the urologist in best advising their patient on the risks and benefits of observation, this chapter discusses the natural history of urinary stones, both naturally occurring stones and the residual fragments present after prior treatment.

## Natural history of asymptomatic renal stones

The worldwide increase in the incidence and prevalence of stone disease has been attributed, in part, to the incidental detection of asymptomatic calculi secondary to escalating utilization of three-dimensional radiographic imaging [1, 2]. For example, an Icelandic population study found the annual incidence of stones among the population increased significantly from 108 to 138 per 100 000 over a 5 year period. However, the increase entirely was due to an increase in incidental stones detected at the time of imaging for a concurrent illness, from 7 to 23 per 100 000 with no significant increase in symptomatic stones [2].

Other observational studies have demonstrated a nearly 10% incidence of asymptomatic stones in the general population and thus some insights into the prevalence of asymptomatic renal stones can be obtained from these screening studies. In a series of 5000 patients undergoing screening computed tomography (CT) colonography urinary stones were found in 7.8% of patients, with a mean size of 3 mm and an average of two stones per patient [1]. Similarly, in a series of 2000 CT scans of kidney donors 9.7% harbored asymptomatic stones [3]. Although not the best imaging study for stone evaluation, a prospective renal ultrasound screening trial of 201 patients in Pakistan without a known genitourinary disease found a 3% rate of asymptomatic renal stones [4].

Once the incidental diagnosis of an asymptomatic stone is made, patients will require counseling regarding the implications and clinical relevance. At least ten studies have reported the outcomes of observing asymptomatic renal stones [1, 5–13] (see Table 63.1). These studies vary in population size and demographics, as well as stone location and number. Follow-up periods for the studies ranged from 1.6 to 10.0 years (median 3.4 years), but collectively they observed the outcome of more than 1800 asymptomatic renal stones, providing significant insight into the natural history of asymptomatic upper tract urinary stones.

Interval growth determined by follow-up imaging was reported in four studies (see Table 63.1). Hübner and Popaczy looked at 62 patients in 1990, with a mean follow-up of 7.4 years. Interval stone growth was seen in 28 (45%) patients and eight (13%) developed into staghorn

**Table 63.2** Summation of risk factors for clinical progression of asymptomatic stones.

| Risk factor | Stone growth | Spontaneous passage | Symptomatic stone event | Surgical intervention |
|---|---|---|---|---|
| Male gender | – | – | ↑ | – |
| Advanced age | – | ↓ | – | – |
| Larger stone size | ↑ | ↓ | ↑ | –/↑ |
| Upper pole/interpolar location | – | ↑ | ↑ | – |

stones [5]. Inci and colleagues followed 27 renal units with 2–12 mm stones every 2 years with a CT scan and found that 30% of stones grew by a mean of 4.4 mm (98% increase in size) at 2 years. Furthermore, 33% had grown by a mean of 7.2 mm (132% increase in size) at last follow-up (mean 4.3 years) [9]. In contrast, a study by Koh and colleagues found that 46% of stones grew, but only by 2.8 mm over 3.8 years [11]. Dropkin and colleagues reported 21% of stones grew by more than 50% of their initial size in 2 years [13]. Thus, the studies demonstrate varying degrees of stone growth over time, with some demonstrating significant stone size increases. When looking at risk factors for stone growth, two studies found no significant association between initial stone size or location and stone growth [9, 11], whereas the third found stones larger than 15 mm to grow at a slower rate than smaller stones [8]. In summation 21–46% of stones are found to grow on repeat observation. Average growth rates range from 0 to 2 mm per year [9].

In the patient with asymptomatic renal calculi undergoing observation, subsequent development of renal colic, flank pain, or other symptoms prompting further medical intervention has been recognized and is of significant concern. In 10 studies, the rate of such symptomatic stone events was 11–54% (follow-up range 1.6–10.0 years) [1, 5–13] with a cumulative event rate of 33% (see Table 63.1). Glowacki et al. estimated the risk of a symptomatic stone episode or need for intervention to be approximately 10% per year, culminating in 49% of patients having a stone event 5 years after their initial diagnosis of an asymptomatic renal calculi [6]. Spontaneous stone passage rates were recorded in eight studies and ranged from 3 to 29% (median 16%, cumulative rate 18%) [5–7, 9–12]. Surgical intervention rates were 5–40% between studies (median 17%, cumulative rate 15%) [1, 5–7, 9–13]. Specifically, the study by Burgher et al. found that 25% underwent surgery at 5 years and 50% at 7 years [8].

The observed differences in reported rates of spontaneous passage versus surgical intervention (e.g. from 3% passage and 19% intervention [10] to 29% passage and 5% intervention [12]), are in part due to differences in patient population such as age, gender, and stone size. Therefore, some work has gone into identifying risk factors of disease progression in asymptomatic renal stones. Studies focusing on risk of symptomatic stone events in patients with incidentally detected renal stones are summarized in Table 63.2.

## Demographic factors

Kang et al. looked at demographic factors affecting subsequent symptomatic stone events in patients with asymptomatic stones. Age, stone history, stone location (laterality and calyceal location), multiplicity, familial history, and body mass index were not found to be significant risk factors; however, men were more likely to have symptomatic stone events then women (hazard ratio 1.52). Furthermore, younger patients were more likely to spontaneously pass stones than older patients [12].

## Size

Stone size appears to be a significant factor for disease progression. Burgher et al. found that 100% of stones over 15 mm at time of detection would grow (71%), cause pain (57%), or necessitate surgery (29%). They also found that stones greater than or equal to 4 mm were 26% more likely to fail observation than smaller stones [8]. Another study found that stones measuring 5 mm or less were significantly more likely to spontaneously pass compared to stones that were larger in size (28 vs. 4%) [11, 12]. However, the authors found no association between stone size and need for intervention [11].

## Location

Prior studies have failed to identify any significant association between stone location and stone symptoms, spontaneous passage, or need for intervention. However, a more recent study by Dropkin et al. reported that upper pole and interpolar renal stones were more likely than lower pole stones to become symptomatic (40.6 vs. 24.3%) and more likely to pass spontaneously (14.5 vs. 2.9%) [13].

## Observation versus treatment

Raman and Pearle conducted a meta-analysis seeking optimum management of lower pole calculi. Their study revealed that patients with lower pole stones larger than 2 cm treated with percutaneous nephrolithotomy experienced less morbidity than those treated with other modalities. However, consistent with other previous studies, they also concluded that lower pole stones less than 1 cm may be observed with equivalent morbidity outcomes as shock-wave lithotripsy (SWL) and ureteroscopy with laser lithotripsy. The authors also noted observation to have the least cost and surgical risk of the available management strategies [14].

It should be noted that while the vast majority of interventions are performed for symptomatic events, not all events were symptomatic. In one study 2% of patients with asymptomatic renal calculi treated with observation developed silent obstruction and hydronephrosis identified on surveillance imaging leading to intervention [13]. Such findings, although rare, support the role for continued imaging observation for patients with asymptomatic renal calculi treated with conservative management. At a minimum, periodic renal ultrasound will provide information on the presence of hydronephrosis with minimal risk and no radiation exposure to the patient.

Although observation is an attractive treatment option for the above-noted reasons, the American Urological Association (AUA) guidelines on the surgical management of stone disease state that there are certain settings for which observation of asymptomatic renal calculi should not be considered. These settings include: cases of associated infection, vocational reasons in which an acute stone event would be detrimental (such as airline pilots, military), and poor access to contemporary medical care [15]. In such clinical scenarios consideration should be given to active surgical intervention to remove the stone.

## Natural history of staghorn calculi

A staghorn calculus is a term used for stones that occupy all or most of the renal collecting system in a branching fashion. These large branching stones are relatively rare, accounting for 1% of all symptomatic first-time stone events [16]. Staghorns most often involve the renal pelvis and extend into the infundibula and calyces [16]. Branched stones that occupy only a part of the collecting system are called branched stones or partial staghorns. Unlike the non-staghorn, nonbranched asymptomatic stones discussed earlier in the chapter these branching stones are often associated with infection and have quite an ominous natural course. If left untreated, a staghorn stone has a high likelihood of resulting in a nonfunctioning kidney, severe systemic infections, malignancy, or even patient death [15, 17–19].

Compelling observational data exist from before the current era of endourology. A study from 1976 looked at 60 staghorn patients treated with observation alone. The overall mortality rate in these staghorn calculi patients treated with observation was 28%, of which nine (15%) patients died of renal failure, four (7%) developed renal pelvis carcinoma, and 16 (27%) life-threatening pyonephrosis [17]. Another study from the same era found that nine of 30 (30%) patients treated conservatively for a staghorn calculus died of renal failure or urosepsis [18]. In a pathology-focused study, examination of kidneys removed due to staghorn stones found that 49% demonstrated significant renal parenchyma pathology. The findings included pyonephrosis (20%), xanthogranulomatous pyelonephritis (8%), severe or end-stage pyelonephritis (13%), end-stage hydronephrosis (7%), and perinephric abscesses (5%) [19]. A more recent study from the early 1990s of patients with conservatively treated staghorn stones found that 36% developed chronic renal failure and 11% died from uremia [20]. Furthermore, in a study from 1995, the early era of endourology, found none of 77 patients treated for staghorn stone and rendered stone-free died of renal disease at a mean follow-up of 7.7 years, compared to one of 35 (3%) with residual stone fragments after treatment and two of three (67%) of those treated conservatively [21].

In light of this unequivocal evidence against observation of staghorn calculi, published guidelines have since strongly advised for the complete surgical removal of staghorn stones in all patients fit to undergo surgery [15, 22].

A caveat in discussing the natural history of staghorn stones is that the most extensive data come from an era where the majority (59–68%) of staghorn stones were infection-stone compositions such as struvite. More contemporary series indicate that metabolic stones now account for 56% of staghorn stones, with calcium phosphate accounting for the majority [19, 23–25]. The natural history of metabolic stones may potentially be different from that of infection stones, and thus the natural history in the current era could differ from decades ago.

A 2015 study looked prospectively at 22 minimally symptomatic or asymptomatic staghorn stone patients who were treated conservatively, either because they were unfit or unwilling to undergo surgery. Among the

17 patients who had a unilateral staghorn stone, recurrent urinary tract infections occurred in seven (41%) patients, one (6%) required dialysis, and none died of renal disease or renal-related conditions at a median follow-up of 6 years. Such observed outcomes are notably better than in prior series. However, among five patients with bilateral staghorn stones, 80% had recurrent urinary tract infections, 20% required dialysis, and 40% died of renal disease [26]. The contemporary results can be compared to a recent series reporting long-term outcomes of percutaneous nephrolithotomy for staghorn stones in patients with reduced renal function at presentation. The authors found that 20% of patients had a decline in renal function postoperatively, but only three of 262 (1.8%) of patients developed end-stage renal failure at 3 years of follow-up [27]. Despite the more recent promising results of observation for staghorn calculi, active treatment is still recommended by the AUA and Endourology Society if the patient is healthy enough for surgical intervention [15]. The guideline recommendations are based on the fact that minimally invasive treatment of staghorn calculi with percutaneous nephrolithotomy is highly successful with minimal morbidity in most scenarios.

## Natural history of asymptomatic ureteral stones

While the renal pelvis and calices are capacious and can frequently accommodate stones without causing significant obstruction, the ureter is smaller in diameter and a stone in this location would be more likely to result in symptoms and/or obstruction. In fact, only 1.1–5.3% of all treated ureteral stones are silent [28, 29]. As previously mentioned, silent ureteral stones have been subsequently found in 2% of patient undergoing surveillance imaging who were on observation for asymptomatic renal stones. The population incidence of silent ureteral stones among subjects without a history of known stone disease is low. Among 5047 patient undergoing screening CT colonography only six (0.1%) were found to have an incidental silent ureteral stone [1]. Given their rare presentation, very limited data exist regarding spontaneous passage rates among asymptomatic ureteral stones with one study reporting one of 40 (2.5%) patients passing their stone before a scheduled surgery date [28]. Wimpissinger and colleagues [30] prospectively looked at 14 asymptomatic ureteral stones. They found 11 (76%) kidneys to be associated with hydronephrosis on imaging and on MAG3 scintigraphy and of the 11 kidneys with hydronephrosis, five (36%) were unobstructed, seven (50%) were obstructed, and two (14%) had no excretory function. There was a positive correlation between stone size and likelihood of obstruction, with larger stones more likely to result in complete obstruction or no excretory function [30]. Based on this limited data, most physicians should consider only a short trial of passage, 6 weeks or less per AUA and Endourology Society guidelines [15], with scheduled follow-up imaging to assess for definitive stone passage if observation is chosen for the asymptomatic ureteral calculi.

## Natural history of symptomatic ureteral stones

Symptomatic ureteral stones often call for intervention given infections, intractable pain, or adverse effects on renal function. It is, however, well documented that a large portion of ureteral stones pass spontaneously. Ample data exist from control arms of trials for medical expulsive therapy on the natural history of passage of symptomatic ureteral stones. A meta-analysis reported in the 2016 AUA and Endourology Society guidelines on surgical management of stone disease looked at 25 studies conducted from 2002 to 2015 on medical expulsive therapy for distal ureteral stones less than 10 mm in size. Combined, 1100 stone patients were in the control arms and underwent trial of passage without medical expulsive therapy. The cumulative stone passage rate in the control arms was 57% (range 4–88%, median 53%). Follow-up in the majority of studies was most commonly 4 or 6 weeks [15]. Fewer data were available on proximal and mid-ureteral stones and thus the guideline panel could not make strong conclusions based on the use of medical expulsive therapy for such stones. However, studies comparing stone passage based on ureteral location found that spontaneous passage occurs in 12–48% of proximal stones, 22–81% of mid-ureteral stones, and 45–96% of distal stones [31–34]. Stones at the ureterovesical junction pass in 43–79% [33, 35].

Stone size is also known to affect likelihood of passage. Ueno and colleges in 1977 [36] correlated stone size on plain X-ray by 1 mm increments with stone passage rate and Coll and colleagues in 2002 [33] similarly correlated the maximal stone diameter in the axial plane on helical CT with passage rates (see Table 63.3).

Factoring in stone size and location, Ahmed and colleges identified that at 45 days the passage rate for stones less than or equal to 5 mm was 50, 93, and 97% for proximal, mid, and distal ureter respectively and for stones greater than 5 mm it was 25, 65, and 95% for the same ureteral segments [31–34].

Additional CT imaging findings, such as higher three-dimensional stone volume and axial surface area, as well

**Table 63.3** Likelihood of ureteral stone passage based on size on imaging.

| | Passage rate (%) | |
|---|---|---|
| Stone size (mm) | Ueno et al. [36], abdominal X-ray | Coll et al. [33], CT |
| 1 | 100 | 87 |
| 2 | 93 | 72 |
| 3 | 87 | 83 |
| 4 | 78 | 72 |
| 5 | 57 | 60 |
| 6 | 35 | 72 |
| 7 | 28 | 74 |
| 8 | 14 | 56 |
| 9 | 0 | 33 |
| 10 | 0 | 27 |

as perinephric fat stranding and tissue-rim sign (potentially signs of stone impaction), have been reported to translate into a lower likelihood of spontaneous stone passage [34, 37–40]. However, data on the effect of hydronephrosis and elevated markers of inflammation on stone passage have provided inconsistent results [34, 38, 41, 42].

Hydration appears to have a limited effect on stone passage. While canine research data suggested that renal increased hydrostatic pressure was a primary driver for stone expulsion, a clinical study on forced intravenous fluid hydration have shown no improvement in spontaneous stone passage rates compared to normal hydration status [43, 44]. Limited data suggest that spontaneous stone passage is less likely in tobacco smokers, especially for stones larger than 4 mm [45]. Finally, a single series suggests that sexual intercourse three or four times a week increases stone passage rate for smaller distal stones [46]. The symptomatic ureteral stone has numerous treatment options including observation, medical expulsive therapy, SWL, and ureteroscopy. As with asymptomatic ureteral stones, if observation is chosen, a scheduled follow-up imaging to assess for definitive stone passage is needed to avoid the serious downstream effects of an obstructing asymptomatic stone [15].

## Natural history of ureteral stones after stent placement

In various clinical scenarios, such as in the setting of an obstructing stone with concomitant infection or deterioration of renal function, insertion of a ureteral stent with planned delayed stone removal is considered the standard of care. In rare instances the obstructing stone may pass while the temporizing ureteral stent is in place; however, such scenarios are not common and limited clinical data exist. Animal studies have shown that the presence of ureteric stents is associated with ureteric dilatation, diminished ureteric peristalsis, and impaired stone passage [47, 48]. Taha et al. report a clinical series where patients were stented for a mean of 3 months for acute obstructing stone indications. A CT scan was performed at follow-up prior to definitive stone treatment. Notably, 41% of the stones were no longer present on follow-up imaging. All the disappearing, or spontaneously passed stones were smaller than 6 mm and 70% were radiolucent on initial CT scout film imaging and thus were potentially uric acid stones. Patients on urinary alkalization therapy were not excluded and therefore stone dissolution may account for some of the missing stones. Among radiopaque stones, only 22% passed, all of them smaller than 6 mm [49]. Such stone passage rates are significantly lower than the 57% or higher spontaneous passage rates among ureteral stones on observation (see Table 63.3) [33, 36]. Thus, it can be concluded that in most scenarios placement of a ureteral stent hinders stone passage.

## Natural history of residual calculi after shock-wave lithotripsy

Treatments of stone disease are among the most common urological interventions, and for ureteral stones shock wave lithotripsy (SWL) is one of the most widely utilized treatment modalities. Therefore, the natural history of residual stone fragments after surgical intervention is of significant concern. As with incidentally identified asymptomatic stones treated with observation, residual fragments after surgical intervention are subject to growth, symptomatic events, and possible need for further surgical interventions. To date, the most data on residual fragments after surgical intervention exist for SWL. SWL by design does not remove stones and leaves the patient prone to residual fragments. SWL fractures the stone into small fragments that must then be expelled naturally down the ureter. Most stone fragments are expelled; however, in the best treatment scenarios at 3 months' follow-up 23–36% of patients will still harbor residual fragments [50–52]. Residual fragments are often treated, with an average of 1.26–1.34 treatments needed to reach a stone-free state, based on size and location [15]. Some authors historically advised for observation of fragments less than 4–5 mm [50].

Of these patients with remaining fragments at 3 months' postprocedure follow-up, the likelihood of eventual stone fragment clearance is low. In fact, Candau and colleagues found that of patients with a 4 mm stone or less at 3 months, 66% still had a stable or larger residual fragment 40 months later [53]. It had been suggested that the presence of non-infection, nonobstructive, asymptomatic postprocedural residual fragments <4 mm could be managed metabolically in order to prevent stone growth adequately, sometimes referred to as "clinically insignificant fragments." However, based on data from Candau and other authors the idea of clinically insignificant fragments should be considered a misnomer [53–55].

At least seven studies have looked at fragment growth after SWL in adult populations (see Table 63.4), with follow-up ranging from 15 to 89 months. Depending on the study, regrowth or increase in size occurred in 2–55% of patients (median 18%) [51, 53, 55–59]. When compared to other surgical interventions such as percutaneous nephrolithotomy or ureteroscopy, symptomatic stone recurrence rates appear to be higher after SWL for similar-sized stones [60]. It has been postulated that high recurrence rates after SWL may be the results of microscopic stone particles migrating to dependent calyces and acting as a nidus for new stone formation. Thus, by increasing the surface area of the original stone, SWL may favor new stone growth through heterogeneous nucleation and crystal aggregation by exposing the stone area to a lithogenic environment [61]. Accordingly, numerous reports suggest that controlling metabolic factors post-SWL substantially affect stone recurrence rates [52, 62, 63].

In addition to contributing to stone recurrence, sizeable residual fragments may cause clinically significant events. As with recurrence numbers, reported symptomatic events and complication secondary to residual stone fragments after SWL range widely from 0 to 59% (see Table 63.4) [4, 57]. In a review by Khaitan and colleges of 75 patients with less than or equal to 4 mm residual stone fragments 3 months after SWL, 24% passed them spontaneously and 17% remained stable, whereas 59% developed one or more complications. Within the 59% with complications, 35 had pain, five had recurrent urinary tract infections, four had ureteric obstruction, and two hematuria [57]. By contrast Osman and colleges followed 175 with less than 4 mm fragments and reported that 21% required subsequent intervention, but all interventions were for stone fragment growth [55]. In a contradictory report by Buchholz and colleges "no patient reported any serious discomfort caused by the residual during the follow-up period" [56]. The differences among studies are likely in part explained by the timing and nature of the follow-up, as design differed notably between the studies. With regards to intervention, not all studies clarify whether interventions were done for a symptomatic event, asymptomatic presence of fragments, regrowth, or combination thereof.

Most prior studies have focused on the outcome of residual fragments less than 4 mm in size, possibly given that this size has been considered "clinically insignificant" and a residual fragment of such size is considered a success after SWL. A more recent study looked at the clinical significance of even smaller fragments. This study compared residual fragments less than or equal to 2 mm to those 2–4 mm after SWL [56]. At 3 months, all fragments 2 mm or less passed spontaneously without a need of an emergency department visit as compared to 76% stone-free rate among 2–4 mm fragments. Furthermore, 19% of the patients with residual fragments 2–4 mm in size presented to the emergency department for treatment of renal colic [64]. The number of stones treated, as well as their size, understandably affects the likelihood of fragment passage [57].

**Table 63.4** Symptoms, intervention, stone-free rates, and stone regrowth after shock-wave lithotripsy.

NR, Not reported.

Factors other than residual fragment size can affect the eventual clinical outcomes. Residual fragment location on postoperative imaging after SWL also appears to affect the likelihood of fragment passage. Zanetti and colleges found that patients with lower pole fragments after SWL only becomes stone free in 39% of cases at 12 months of follow-up as compared to 59% of interpolar calyx fragments and 70% of upper pole calyx fragments [51]. Similarly, looking at residual fragments 5 mm or less, Buchholz and colleges found that 2.5 years after SWL 12.5% of patients still harbored residual fragments. All upper pole, interpolar, and renal pelvis stones had cleared and two-thirds of the remaining stones were in lower pole calyces and one third were in the proximal ureter.

Finally, expulsion of fragment is inherently dependent on the absence of distal obstruction, such as another stone or ureteral stricture. In fact, the AUA/Endourology Society guidelines statement on the surgical management of stone disease states that SWL should not be performed in the presence of distal of obstruction.

## Natural history of residual calculi after ureteroscopy

Although SWL has historically been the most frequently utilized treatment modality for upper tract stone disease, due to high single treatment success rates and low overall morbidity, ureteroscopy has overtaken SWL as the preferred treatment modality. With ureteroscopy, stones are extracted, fractured, and extracted or dusted with the fragments left to pass spontaneously similar to SWL. Based on ureteroscopic technique as well as timing and type of follow-up imaging, stone-free rates have been reported anywhere from 53 to 97% [65]. Given the potential for deleterious effects observed for post-SWL residual fragments, it is important to identify if the same concerns hold true for postureteroscopy residual fragments. Unlike SWL where multiple studies are available, limited data exist on the fate of residual fragments after ureteroscopy (see Table 63.5).

Rebuck and colleagues looked at 51 patients with fragments of 4 mm or less after ureteroscopy followed with routine serial CT scans over 19 months. The authors found that 22% of the patients spontaneously passed their residual fragments, 19% had a symptomatic event, and the remaining 59% retained their fragments without symptoms. The patients who developed symptomatic events had interval growth of fragments on CT scans leading up to the event, whereas those who remained asymptomatic had no interval growth [66]. Chew and colleges performed a multi-institutional retrospective study on 232 patients with any size of fragment after ureteroscopy. The authors reported higher symptomatic event and intervention rates than previous studies. Despite no difference in the likelihood of passage when comparing fragments smaller or larger than 4 mm, the larger fragments were more likely to grow with time, were associated with significantly more complications and required more re-interventions. Fragments smaller than 2 mm were less likely to grow compared to larger fragments, but were just as likely to pass, cause complications, or lead to interventions. Of note, the authors found that dusting versus active extraction of fragments did not statistically affect the risk of re-intervention [67]. Based on these findings, removal of residual fragments after ureteroscopy noted on follow-up imaging should strongly be considered if they are 4 mm or larger in size.

## Natural history of residual calculi after percutaneous nephrolithotomy

Percutaneous nephrolithotomy offers the highest stone-free rate of any procedure [15]. When residual fragments are identified with postoperative imaging they are frequently removed with a second-look percutaneous nephrolithotomy or ureteroscopy. However, despite the surgeons' best efforts, residual fragments after percutaneous nephrolithotomy do occur. Ganpule and Desai reported a series of 187 patients with residual fragments after percutaneous stone removal, of which 67% of patient passed their fragments in the first 3 months. Fragments less than 25 mm$^2$ in size and those situated in the renal pelvis had the best chance of clearance [68]. Other studies have looked at the longer-term clinical

sequelae of residual fragments after percutaneous nephrolithotomy, with symptomatic events occurring between 26 and 43% of cases (see Table 63.6) [68–71]. Raman and colleagues identified that on multivariate analysis only maximum residual fragment size larger than 2 mm and location in the renal pelvis or ureter independently predicted a symptomatic stone event. In the same study 8% of patients with residual fragments less than 2 mm in size underwent surgical retreatment compared to 53% of patients with residual fragments greater than 2 mm. Thus, they concluded that second look flexible nephroscopy may be of benefit in patients with residual fragments larger than 2 mm or in those with fragments located in the renal pelvis or ureter [71]. Xin and colleagues verified these findings regarding residual fragment size after percutaneous nephrolithotomy and need for subsequent intervention. Interestingly, the authors added that in addition to residual stone fragment size, a past history of SWL increased the risk of symptomatic stone events for residual fragments after percutaneous nephrolithotomy [69].

Only one study has reported stone regrowth rates after percutaneous nephrolithotomy. In the study by Altunrende and colleagues stone regrowth after percutaneous nephrolithotomy occurred in 21% of patients followed over 28 months [70]. These findings are consistent with a study comparing new stone formation after either SWL or percutaneous nephrolithotomy, which found 22% of patients developing new renal stones within 2 years of the procedure [60].

## Natural history of asymptomatic stones and residual fragments in children

The bulk of the abovementioned literature comes from adult patients; however, data are emerging on observation of asymptomatic stones in children. A retrospective study of renal ultrasound studies found that asymptomatic renal stones in children will neither grow nor cause symptoms in (21%), not pass spontaneously (5%) or require intervention (25%) [72].

Recently two studies have also been published on residual fragments after stone treatment in children. Dincel and colleges followed 22 children aged 1–17 years (mean 9 years), who had residual fragments of 4 mm or less after SWL, percutaneous nephrolithotomy, or ureteroscopy. Spontaneous passage of the residual fragment occurred in 26% of the children regardless of the primary treatment. Acute symptoms occurred in 40% of children with residual fragments after surgical intervention. Stone growth occurred in 21%. Subsequent surgical intervention was needed in 29% of the children for either acute symptoms or stone regrowth [73]. Similarly, El-Assmy and colleges looked at 42 children with a median age of 6 years (range 1–14 years) who had less than or equal to 4 mm residual fragment after either SWL or percutaneous nephrolithotomy. While 69% of the children passed fragments spontaneously or had asymptomatic fragments without growth, 32% had an acute stone event or significant stone growth. Furthermore, secondary surgical procedures were required in 16% of the children [74]. Taken in total, it must be concluded that small residual fragments are quite clinically relevant in children and should be followed closely.

## Conclusion

The incidence of asymptomatic stones is increasing, most likely due to the wide availability of sensitive imaging techniques. Observation of asymptomatic renal calculi is a reasonable treatment option, but the patient and physician must be aware of the risks of stone growth, symptomatic events, and need for subsequent surgical intervention. The risk of the asymptomatic calculi becoming symptomatic in both the adult and pediatric population is dependent on many factors, which must be weighed when determining if observation is appropriate. Likewise, when residual fragments are noted after surgical intervention, there is a risk of subsequent stone regrowth or symptomatic events. However, with appropriate counseling and follow-up the asymptomatic stone can be safely observed in the appropriately selected patient.

# Initial Choice of Therapy in the Stone Patient

*Peter L. Steinberg*[1] *& David M. Hoenig*[2]

[1] *Beth Israel Deaconess Medical Center, Boston, MA, USA*
[2] *The Arthur Smith Institute for Urology, Zucker School of Medicine at Hofstra/Northwell, Lake Success, NY, USA*

## Introduction

Urolithiasis is a prevalent condition, afflicting nearly 10% of the US population [1]. Cost estimates for stone management range from US$2 billion to $10 billion annually in the American healthcare system [1, 2]. As the front line in managing stone disease, the urologist is armed with numerous tools to manage a patient presenting with a urinary stone. This chapter will focus on adult patients with "normal" renal anatomy, as stones in aberrant urinary systems are discussed in Chapters 67–71. Since the focus is elective stone management, patients presenting with sepsis, renal failure, or intractable pain are not discussed, as these situations dictate urgent urinary tract decompression with either ureteral stenting or percutaneous nephrostomy and are described in Chapter 66. The prime modalities discussed are shock-wave lithotripsy (SWL), ureteroscopy/ureterorenoscopy (URS), percutaneous nephrolithotomy (PCNL), medical expulsive therapy (MET), and observation.

## Overall approach

Most urologists confront ureteral stones acutely and renal stones in a less urgent fashion. As such, the primary issue facing the urologist treating a patient with a ureteral stone, after insuring appropriate pain management, renal function, and that systemic inflammatory response syndrome (SIRS)/sepsis is not an issue, is to determine if spontaneous passage is likely or not. When faced with a renal stone, decision-making is often less pressed and selecting the optimal surgical approach is paramount to assure the best chance of success.

A recent *New England Journal of Medicine* article by Smith-Bindman et al. provided some insight into the rate of urgent intervention needed when patients present to the emergency department with renal colic [3]. Nearly 10% of patients seen initially for renal colic require hospital admission for pain management and/or surgical intervention. In the month following initial evaluation, another 10–15% will present back to the emergency department and one-third of these patients will require hospital admission [3]. This highlights that although some patients need urgent intervention, many will semi-electively end up seeing a urologist where a plan for observation or intervention will be created.

## Ureteral stones

Although some data have come to light questioning the efficacy of MET [4], the general paradigm for managing ureteral stones involves observation with or without MET for most stones and if that fails proceeding to a URS or SWL. Rarely will an antegrade/percutaneous or laparoscopic/robotic/open approach be needed for these stones.

### Distal ureteral stones

Stones in the distal ureter are among those with the highest rate of spontaneous passage [5, 6]. The ureterovesical junction (UVJ) remains a common site for stones to become lodged, as it is the narrowest part of the ureter (Figure 64.1a). Generally speaking, smaller stones that are further along the ureter have a greater chance of spontaneous passage than larger stones in a

more proximal location. Although it is difficult to tell the exact fate of any given stone, there is ample evidence that the majority of stones under 4–5 mm often pass [5, 6]. Additionally, stones that have not passed within 4–6 weeks seldom do so [5].

A trial of MET is warranted in nearly all patients with an uncomplicated distal stones under 1 cm. Two meta-analyses support the role of both alpha-antagonists and calcium channel blockers (CCBs) to increase the number of stones passed and to hasten the speed of stone passage [7, 8]. A review from Hollingsworth et al. suggests a 65% increased rate of stone expulsion with either agent, and the number needed to treat to lead to one additional stone expulsion was four [7]. A study from the emergency medicine literature, pooling data from 16 alpha-blocker studies and nine CCB studies, shows a 59% greater rate of passage with alpha-blockers and a 50% greater rate of passage with CCBs [8]. The number needed to treat in this study for alpha-blockers was 3.3 and for CCBs it was 3.9 [8]. Based upon their own analysis of the data, the American Urological Association (AUA) suggests alpha-blockers are the preferred agent for MET, primarily due to their lower rate of side effects than CCBs [6].

Recently, a well-powered study from the United Kingdom suggested that MET with either alpha-blockers or CCBs provides minimal benefit over observation [4]. This study randomized over 1100 patients to placebo, nifedipine, or tamsulosin and showed that 80% of patients in each arm did not require surgical intervention. Interestingly, this trial accrued patients with stones in all ureteral locations while prior work has focused on the distal ureter, and had only one-third of enrolled patients with stones >5 mm in size [4]. This high-quality trial is the best-powered study to date on MET; however, there are some legitimate criticisms of the study design. Given the familiarity urologists have with alpha-blockers and their excellent safety profile, it seems a trial that is both well powered and with a patient population similar to the prior studies with equivalent percentages of distal stones >5 mm may be needed to curtail the practice of MET.

Two sets of AUA guidelines on the surgical management of stones have clearly demonstrated that URS is the most efficacious means of managing a distal ureteral stone [5, 6]. Success rates for URS are well over 90% in most series and SWL has a clearance rate much lower, often in the 60–70% range: this is clearly dependent on a number of factors including the lithotripter used. Overall, a patient undergoing a SWL for a distal stone will require 1.3 procedures for clearance, as compared to a patient undergoing a URS [5, 6]. Both procedures are relatively safe, with URS associated with a <5% risk of several ureteral injury in modern series [6]; however, the common use of ureteral stents after URS is a continuing source of morbidity and often dreaded by patients who are recurrent stone formers.

Given this information, it seems apparent that a trial of MET is appropriate in many patients with uncomplicated distal ureteral stones. If MET fails, the choice of

URS or SWL for a distal ureteral stone lies with the available expertise and equipment, and with the patient after an informed discussion of the risks and benefits of each modality. Armed with the knowledge that both modalities lead to high rates of stone clearance, additional factors such as the potential need for stenting, type of anesthetic used, and complication profile of each procedure can be used to guide the choice of therapy.

## Proximal and mid-ureteral stones

Optimal management of these stones depends heavily upon the size and density of the calculus in question [9]. As described above, larger and more proximal stones are associated with a lower rate and longer time to spontaneous passage than smaller and more distal stones [5, 6]. Management of mid- and proximal ureteral stones is slightly different from that of distal stones, with the largest difference being the lack of evidence for MET in mid- and proximal ureteral stones as it has not been thoroughly tested. A study by Pickard et al. would suggest there is no role for MET in these stones, although it also suggested no role for MET in distal stones [4]. Operative intervention consists primarily of SWL or URS, although there is a select role for antegrade approaches to large and complex proximal calculi.

Once again, pooled data from multiple studies are provided by the 2007 and 2016 AUA guidelines delineating outcomes in the management of proximal and mid-ureteral stones [5, 6]. Overall, URS is associated with improved stone-free rates in both locations, with nearly 90% success in many studies, while SWL again has a lower stone-free rate in the 70–85% range [5, 6]. This relationship holds until stones get over 1 cm in size and then outcomes begin to converge, with roughly 80% stone-free rates for both modalities [5, 6]. The rate of secondary procedures is higher when SWL is used for stones under 1 cm, as in the distal ureter [5, 6].

One unique issue with SWL in the mid ureter involves the bony pelvis interfering with visualization and treatment of the stone (Figure 64.2). In some lithotripters, a prone position must be used to ensure the stone is in the ideal position for treatment, and localization of the stone may be challenging due to the bony structures.

An additional consideration to aid in selecting optimal initial therapy for proximal ureteral stones focuses on the costs incurred with treatment. A cost analysis from Lotan et al. shows that URS is less costly than SWL for proximal stones when performed primarily [10]. When considering the higher rate of adjunctive procedures for SWL compared with URS, the cost differential is even greater and is something to potentially consider when deciding how to approach the patient with such a stone [10].

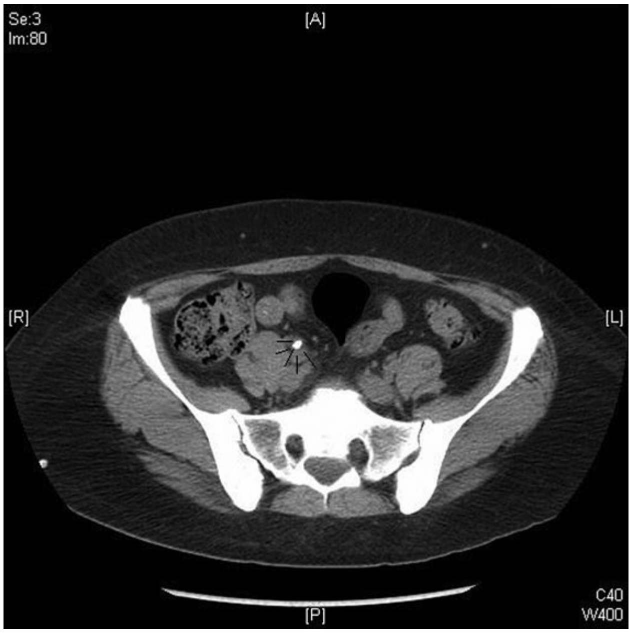

**Figure 64.2** CT of right mid-ureteral stone (demarcated by lines). Note the presence of the sacrum and iliac bones posterior, which can interfere with shock transmission.

In select cases of very large stones in the proximal ureter, or stones which are heavily impacted and do not permit retrograde access, a patient can be offered an antegrade procedure for clearance [11]. Both rigid and flexible nephroscopy can be used to approach the ureteropelvic junction and proximal ureter. In addition, following treatment of the stone, fragments can be removed via the percutaneous tract, obviating the need for passage.

### Summary

The patient with an uncomplicated ureteral stone is best managed initially with a period of observation, with or without MET. If surgical therapy is indicated, URS generally leads to higher stone-free rates than SWL, though is associated with a higher rate of complications and is more invasive. A frank and informed discussion about the risks and benefits of each surgical approach, individual patient factors, and consideration of stone composition, size, and location, are the optimal means of choosing the most appropriate surgical stone therapy (Figure 64.3).

## Renal stones

As in the ureter, both stone size and location are critical to the choice of optimal initial therapy in the renal stone patient. Unlike the ureter, where anatomy is generally straightforward and of little consequence for surgical

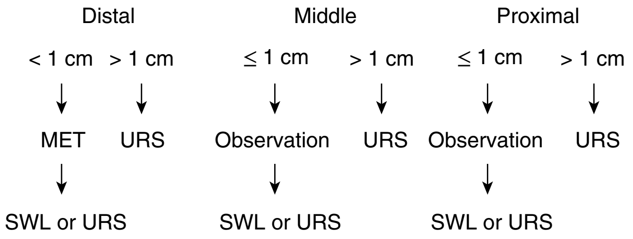

**Figure 64.3** Ureteral calculi: optimal initial management strategy.

planning, intrarenal anatomy and patient body habitus can play significant roles in deciding which treatment options are best for each patient. Additionally, stone composition is vitally important, as it heavily impacts the outcomes of SWL, in particular. Here the choice of management will generally range from observation to SWL, URS, and PCNL.

For renal stones 1 cm or smaller that are asymptomatic, non-obstructing, and not associated with infection, a reasonable strategy is one of observation. Periodic assessment of the patient for symptoms and the stone for growth with a plan for deferred management is reasonable. Following the stone with plain radiography, renal ultrasound, both, or a low-radiation-dose computed tomography (CT) at semi-annual or annual intervals is a sensible approach. A recent study from the Dartmouth group suggested that stones in the lower pole are substantially less likely to become symptomatic than in all other renal locations: 24% for the lower pole versus 41% for the remainder of the kidney [12]. Given that roughly 30% of patients in this study became symptomatic or needed intervention over an average of 41 months of follow-up, this may allow better risk stratification among patients on surveillance.

## Renal stones 1 cm or smaller in size

There are three options for managing a renal stone up to 1 cm in size: SWL, URS, and PCNL. We will consider lower pole stones separately later in the chapter (Figure 64.4). SWL is still a first-line option for these stones, especially for a stone of low attenuation on CT scan (<800–900 Hounsfield units density), in an interpolar, upper pole, or renal pelvic location, and in a calyx with a normal infundibulum [9, 13–15].

Highest clearance is achievable with stones in the renal pelvis, with reported success rates of 80–90% [13–15]. Although CT does not perfectly predict the composition of stones, stones with higher Hounsfield units are less susceptible to management with SWL, and this is a reasonable means of stratifying treatment [15, 16]. Additionally, body habitus in terms of the skin–stone distance is a critical factor in appropriate patient choice for SWL, with a skin–stone distance of over 10 cm associated with poorer outcome for that procedure [15, 16].

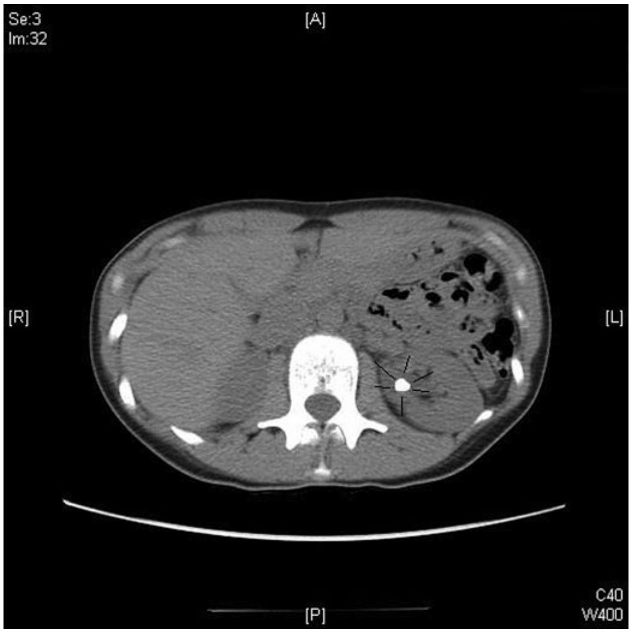

**Figure 64.4** CT scan of left renal pelvic stone (demarcated by lines).

URS is a reasonable choice for many renal stones, as modern ureteroscopes can reach the entire collecting system and displace a stone to a readily accessible location for lithotripsy or basket removal. This achieves equivalent outcomes to SWL for calculi located within the kidney across all stone compositions, with very low morbidity [15]. Stone-free rates of approximately 80% can be expected for renal stones of 1 cm or smaller in size treated by URS [15]. In the patient with a high-attenuation stone or a large skin–stone distance, URS is preferred to SWL as the difference in success rate is significant [15].

Finally, PCNL yields very high clearance rates for small renal calculi, but may be an overly morbid procedure for a stone of 1 cm or less considering the success rates achieved with less invasive procedures [15]. In general, PCNL should not be considered as optimal initial management in renal stones of 1 cm or less, unless extraneous factors such as associated conditions or abnormal anatomy are at play.

## Renal stones 1–2 cm in size

For renal stones, SWL remains a treatment option in this size range. A nomogram developed by Kanao et al. offers good estimates of stone clearance and can help guide decision-making [17]. For a renal pelvic stone, the chances of clearance at 3 months after a single SWL session are 43% for stones of 16–20 mm and 64% for stones of 11–15 mm in size [17]. For stones located in a calyx, the comparable stone-free rates are 35 and 57%, respectively [17].

As already stated, advances in equipment for stone management over recent years mean that virtually any location in the kidney can be readily accessed with flexible ureteroscopes. Concomitantly, there has been an effort to manage larger renal calculi with URS to assess its role compared with the more invasive PCNL (Figure 64.5). Several studies have sought to compare URS and PCNL in this size range, confirming that the stone-free rate is higher with PCNL, as expected, as is the complication rate [18–20].

When deciding how to manage these stones, the decision should largely rest on the patient's goals of therapy and possible complications of treatment. For example, if the patient's priority is to be stone free with the greatest degree of success in the face of high stone density or lower pole location, PCNL would be the ideal choice. Yet if the stone has favourable characteristics that might favor a less invasive alternative, such as renal pelvis location, low Hounsfield units density, and – in the case of SWL – low skin-to-stone distance, SWL or URS may offer a better alternative. Unfortunately, established Level 1 evidence is somewhat lacking, so to definitively answer the question for the population of patients with this stone size cannot be readily done; as a result, individual patient and

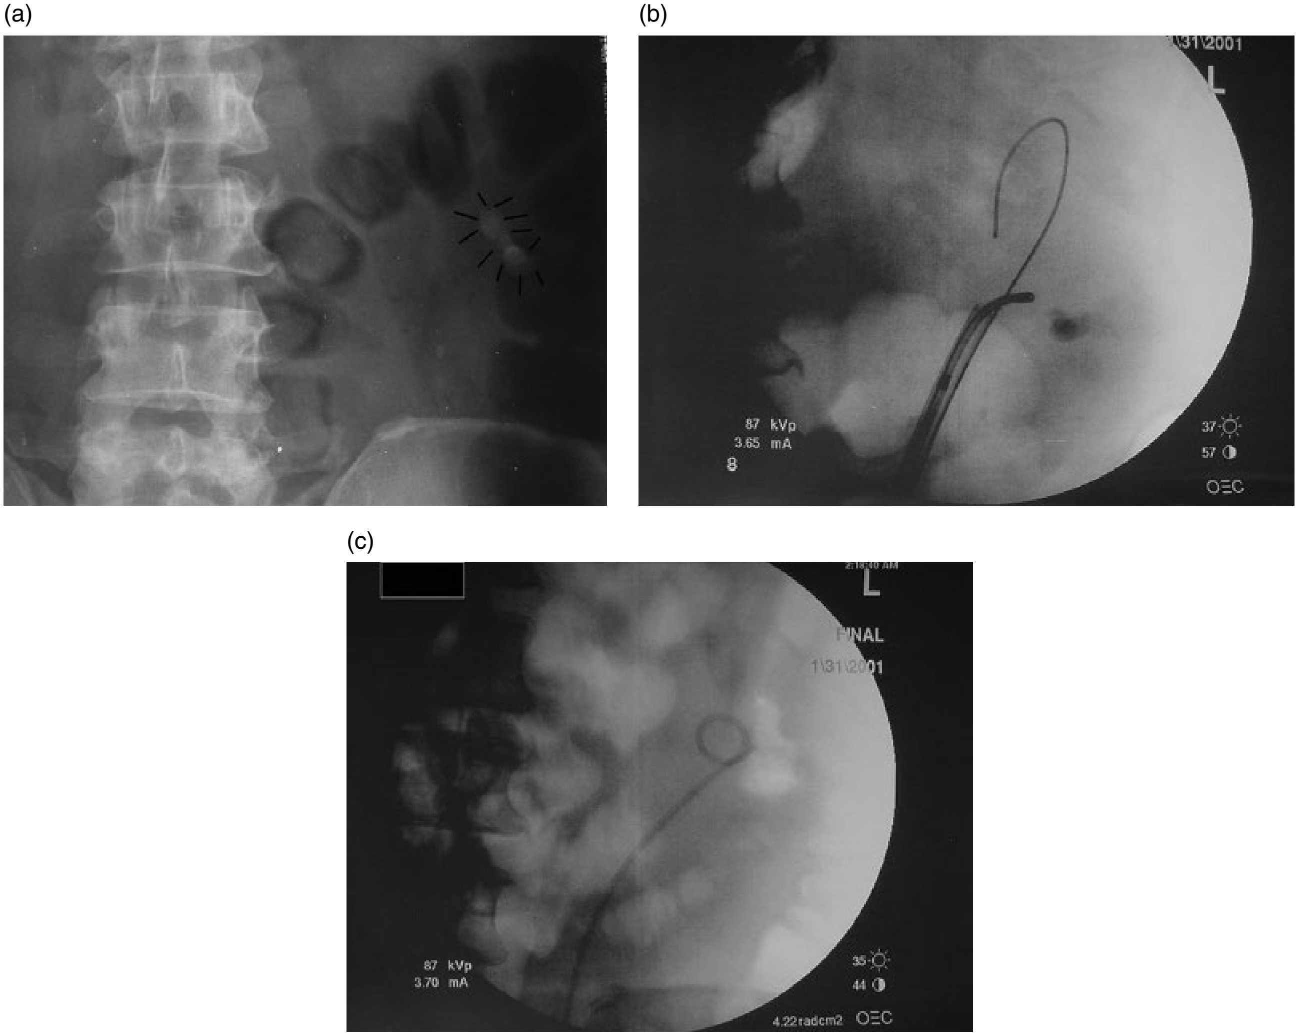

**Figure 64.5** (a) Fluoroscopy of left partial staghorn renal stone (demarcated by lines). (b) Fluoroscopy during URS of left partial staghorn renal stone. Mid procedure, note clearance of stone is underway. (c) Fluoroscopy during conclusion of URS with stent in position and stone cleared from lower pole.

stone factors are the critical data points to consider when counseling patients and determining therapy.

## Renal stones greater than 2 cm in size

When approaching stones greater than 2 cm in size, the success rate of PCNL is unparalleled compared with the alternatives. Both SWL and URS have been utilized with stones of this size, but clearance often requires multiple procedures to achieve stone-free status, whereas PCNL still has a high rate of success with one procedure.

The nomogram by Kanao et al. suggests clearance for renal stones greater than 2 cm in size using SWL is 30% for renal pelvic stones and 23% for calyceal stones [17]. Likewise, for URS stone clearance is feasible for stones over 2 cm in size, but this requires an average of 2.3 URS procedures per patient [19]. In the Lower Pole I cohort, six of seven patients with stones greater than 2 cm in the lower pole were cleared with PCNL, whereas only one in seven patients were cleared with SWL (Figure 64.6) [20].

Clearly, for staghorn calculi and assuming that adequate renal function is present, PCNL is the mainstay of treatment, and can involve multiple access tracts and/or flexible nephroscopy to achieve ultimate success. Procedures such as laparoscopic and open pyelolithotomy/nephrolithotomy are typically reserved for unique situations in the current era, including aberrant anatomy or lack of appropriate instrumentation (Figure 64.7). Stone-free rates approach nearly 80% with a single percutaneous procedure even for such complex cases [21], and can reach up to 95% when flexible scopes and laser lithotripsy are included in the procedure [21].

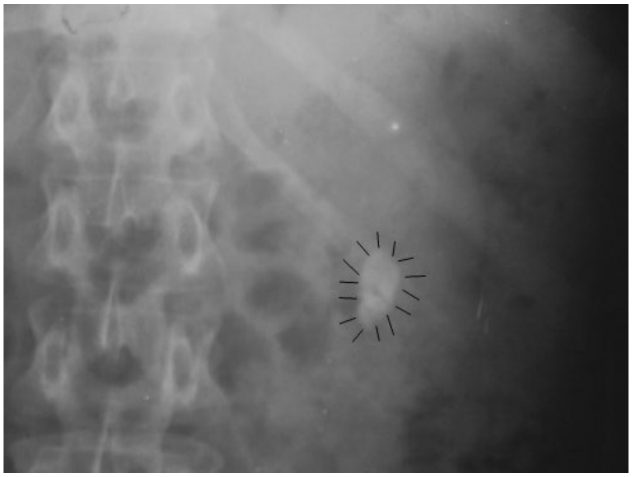

**Figure 64.6** Fluoroscopy of large left lower pole stone (demarcated by lines).

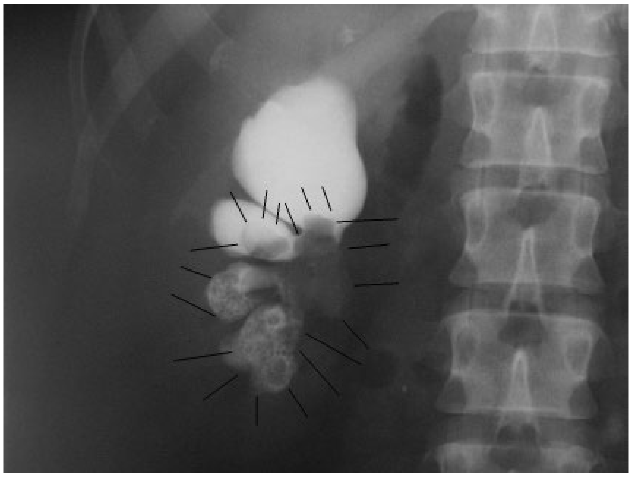

**Figure 64.7** Fluoroscopy during intravenous urography showing large right staghorn renal calculi (demarcated by lines) manifesting as filling defect occupying lower and mid calyces, and renal pelvis.

## Lower pole stones

The lower pole presents a unique anatomic entity in many renal units. Factors such as the width and length of the infundibulum and the angle between the infundibulum and the pelvis can greatly influence surgical outcomes. Although SWL, URS, and PCNL can all be used to manage stones in this location, there are a few broad themes that resonate throughout several trials focusing on this unique location [22]:

1) SWL is associated with the worst outcomes of all modalities.
2) PCNL is associated with the highest stone-free rates of all modalities.
3) URS can compete with PCNL for many stones under 2 cm in size; however, as stones get larger, PCNL is clearly the dominant modality.

## Summary

For renal stones, several variables contribute to the decision as to which stone therapy is optimal for initial management. For asymptomatic stones of 1 cm or smaller in size, a trial of observation is certainly reasonable, although patients should be aware that stones often require treatment or become symptomatic with the passage of time. For stones of 1 cm or smaller in size that warrant treatment, SWL and URS are associated with fair-to-moderate clearance rates and relatively low morbidity. As stones increase in size, especially with a lower pole location, PCNL becomes the most important means of treatment. As stones increase in size over 2 cm, PCNL is the preferred means of management (Figure 64.8).

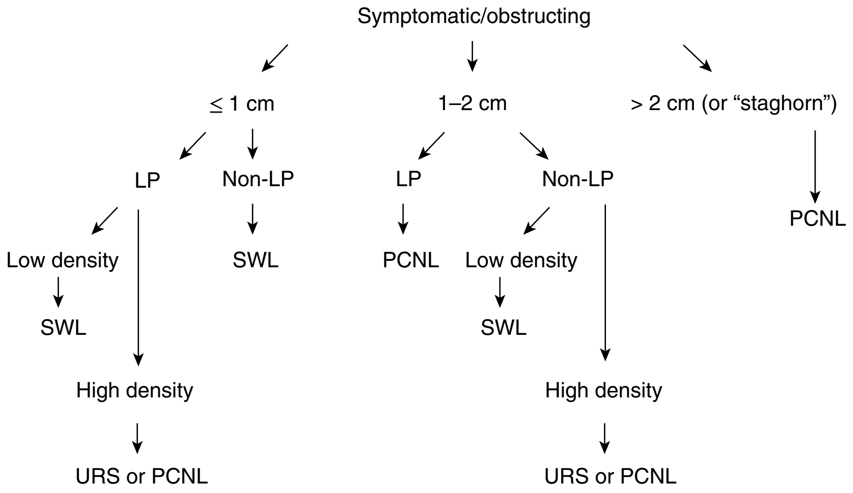

**Figure 64.8** Renal calculi: optimal initial management strategy. LP, lower pole.

## Stones in calyceal diverticula

Stones presenting in a calyceal diverticulum are an infrequent occurrence, and may or may not be symptomatic. Treatment options available for these calculi include SWL, URS, PCNL, and laparoscopic approaches [23–26]. Since this condition is relatively rare, robust data comparing treatment modalities are lacking. Generally SWL will be the least successful means of managing these stones, as the narrow diverticular neck will often preclude passage of all but the smallest fragments. Still, there is a recognized symptomatic improvement in some cases managed by SWL in which colic is the presenting symptom. URS is also efficacious, especially when the diverticulum has a narrow and stenotic neck, hindering passage of fragments after SWL [24, 26]. Using both the flexible ureteroscope and the holmium laser, many of these diverticula can be cleared of their stone burden, with smaller stones again being more amenable to successful clearance.

In the case of a posterior diverticulum, PCNL is an excellent means of accessing the diverticulum, as well as clearing its stone burden and possibly ablating the lining of the diverticulum [23, 26]. Finally, in the event of an anterior diverticulum, a laparoscopic approach has been successfully applied and thus offers an additional treatment option to the percutaneous approach [23, 26].

## Laparoscopic and open stone surgery

The advent of SWL, smaller ureteroscopes, and PCNL has essentially rendered conventional stone surgery obsolete. Nonetheless, circumstances do arise, though rarely, where a laparoscopic or open approach is indicated [27]. For ureteral calculi, operative intervention is rarely needed; however, large impacted stones that fail SWL, URS, or antegrade removal would be candidates [26]. For such stones a laparoscopic/robotic approach can be utilized in lieu of an open ureterolithotomy [27].

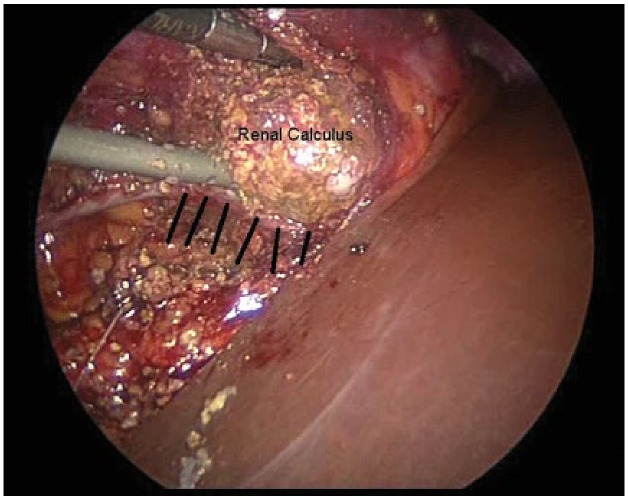

**Figure 64.9** Intraoperative view during laparoscopic pyelolithotomy. The stone is visible as it is being extracted, while the lines demarcate the edge of the pyelotomy incision.

For renal stones, an open or laparoscopic approach can be considered in select circumstances as well (Figure 64.9). In the event of failed PCNL, SWL, or URS, especially after multiple procedures, there is a role for formal operative intervention [27]. Additionally, in the event of a staghorn calculus where clearance seems unlikely in a reasonable number of minimally invasive procedures, open or laparoscopic surgery is an option [27]. Occasionally concomitant surgery on an unrelated organ system would be an indication to perform an open procedure on a large renal stone, as would concurrent surgery to repair a ureteral stricture [27]. Finally, some patients' body habitus precludes fluoroscopy, endoscopy, or positioning for SWL and thus leaves the surgeon with no choice but an open or laparoscopic approach to a urinary stone [27].

## Conclusions

The modern urologist has a wide range of operative and nonoperative tools at his disposal to manage renal and ureteral stones. Nearly all ureteral stones can initially be observed, with or without MET. For distal stones, URS provides the highest stone-free rates, while in the upper ureter SWL competes with URS, especially as stones get larger. In the kidney, SWL is still a useful technique, especially when patients are well selected for therapy. URS is a versatile means of managing many renal stones, although as stones get larger, PCNL maintains a dominant position in having the best stone-free rates, especially in the lower pole.

## Anatomic changes during pregnancy

Pregnancy induces a number of anatomic changes within the urinary tract. Renal size increases secondary to an increase in renal vascular volume and an increase in the renal interstitial space. Hydronephrosis of varying severity is experienced by approximately 90% of pregnant women by the third trimester. The hydroureter extends to the sacral promontory and is typically absent more distally. The hydroureteronephrosis of pregnancy results primarily from compression of the gravid uterus [1]. Physiologic hydronephrosis can affect 90% of right kidneys and up to 67% of left kidneys [2]. The hydroureter is more prevalent and severe on the right side, secondary to uterine dextrorotation, as well as a pressure-reducing effect of the sigmoid colon on the left side. The ureteric smooth muscle relaxation due to increased levels of progesterone has also been implicated in the development of gestational hydronephrosis [3, 4]. However, this mechanism may contribute to the early development of hydronephrosis, between 6 and 10 weeks of gestation, while the mechanical factor remains the major cause thereafter. Support for a primarily mechanical theory includes absence of urinary tract gestational ureteral dilation below the pelvic brim in patients with a pelvic kidney and in those who have undergone previous urinary diversion. The bladder is displaced anterosuperiorly by the gravid uterus, bladder capacity increases, and the detrusor muscle becomes relatively hypotonic and has decreased sensation (Table 65.1). The urothelium becomes congested and hyperemic.

## Physiologic changes during pregnancy

Pregnancy induces physiologic changes in many organ systems, including the renal system (Table 65.2). Glomerular filtration rate (GFR) and renal plasma flow increase by 40–65% and 50–85%, respectively [5], secondary to an increase in the cardiac output and decrease in the renal vascular resistance. Creatinine clearance increases by up to 50% [6], leading to lower serum creatinine and urea levels, a higher level of filtered glucose and glucosuria, and higher level of urine sodium, calcium, uric acid, citrate, magnesium, and glucosminoglycans. Enhanced renal filtration additionally affects dosing of antibiotics as well as anesthetic agents. Other nonrenal systems undergo physiologic changes as well.

## Mineral metabolism and stone formation during pregnancy

The homeostasis of urolithiasis-promoting and -inhibiting factors is altered in pregnancy. Placental 1,25-dihydroxycholecalciferol increases intestinal resorption of calcium as well uptake of calcium from bone. The increase in absorbed calcium is offset by an increase in GFR and subsequent increased filtered load of calcium. Parathyroid hormone secretion is decreased, suppressing the tubular resorption of calcium. Thus, serum calcium levels generally remain unchanged and hypercalciuria occurs. Uric acid and oxalate excretion is increased due to increased GFR, and fetal and dietary factors [6–8]. Hypercalciuria,

uricosuria, and oxaluria all create a favorable environment for renal calculus formation.

Pregnancy, however, is not associated with an increased incidence of urolithiasis compared to the nonpregnant population [9, 10]. This is most likely explained by the increase in filtered citrate, magnesium, and glycosaminoglycans [6–8], all of which are known inhibitors of crystal aggregation and growth.

Renal calculi during pregnancy are documented to be composed primarily of calcium phosphate (74%) and calcium oxalate (26%) [11].

Calcium supplementation during pregnancy is associated with a reduction in the risk of preeclampsia, maternal morbidity and mortality, and preterm labor [12–14]. There is evidence that calcium supplementation during pregnancy may however be associated with a slight increased risk of urolithiasis [14].

## Incidence

The incidence of symptomatic urolithiasis in pregnancy is between 1 in 244 and 1 in 2000 pregnancies [15–17]. The overall incidence of urolithiasis is uncertain, but is estimated to be higher, as some asymptomatic renal calculi may remain undetected. There are no observed differences in the rate of urolithiasis between pregnant and nonpregnant women [18, 19].

The average age of presentation is 27 [20] with 80–90% of cases detected during the second and third trimesters. Urolithiasis seems to be higher in multiparous women, in white patients, and in patients with a history of hypertension and renal disease [20, 21]. Ureteral calculi present twice as often as renal calculi [22, 23]. Up to 30% of patients have a history of stone disease [24].

## Presentation

Symptomatic pregnant patients may present with abdominal or flank pain (85–100%), gross (15–30%) or microscopic hematuria (95–100%), lower urinary tract symptoms, urinary tract infection, preeclampsia, and premature labor [25–27]. Nausea and vomiting are invariably present as well. A comprehensive differential diagnosis of abdominal pain during pregnancy is given in Table 65.3.

Acute abdominal or flank pain in pregnancy presents a unique diagnostic challenge. The clinician has to consider anatomic alterations induced by pregnancy that can lead to various conditions mimicking each other. For example, the appendix can be displaced superiorly after the first trimester and appendicitis may mimic pyelonephritis or cholecystitis [28].

## Diagnostic tests

### Imaging and radiation exposure

Accurate diagnosis of abdominal pain in pregnancy largely depends on diagnostic imaging. The necessity of diagnostic imaging and exposure to ionizing radiation is commonly anxiety-provoking for both patients and clinicians. Use of the ionizing radiation needs to be avoided whenever possible, due to its potential teratogenic effects. When its use is unavoidable, a detailed discussion with patients is required, carefully explaining the

**Table 65.3** Differential diagnosis of acute abdominal pain in pregnancy.

| Urologic causes | Gynecologic and obstetric causes | General surgical causes |
|---|---|---|

potential risks associated with its use. Application of techniques to reduce radiation dose is mandatory. The delivered dose of radiation should be as low as possible, while maintaining the quality of diagnostic image that is useful for diagnosis. Effects of ionizing radiation on the fetus can be categorized into four classes: intrauterine fetal death, fetal malformation, disturbance of growth and development, and mutagenic/carcinogenic effect [29, 30]. The risk of exposure is also dependent on the dose of the radiation and fetal gestational age [31].

The radiation dose is measured in Gray units (Gy, SI system), representing the amount of ionizing radiation absorbed by tissue. Previously, the radiation dose was measured in rads (1 Gy equating to 100 rads), representing the radiation dose delivered and not necessarily absorbed by the tissues. The delivered fetal dose for each diagnostic imaging procedure varies according to the technique used (Table 65.4) and maternal body configuration. Most diagnostic procedures deliver fetal doses below 50 mGy [32]. This dose of radiation has not been associated with an increase in fetal anomalies or pregnancy loss [33]. The American College of Obstetricians and Gynecologists recommends that "women should be counseled that the X-ray exposure from a single diagnostic procedure does not result in harmful effects" [33].

The effects of radiation depend on the fetal gestational age [31]. Fetal tissues are most susceptible to ionizing radiation during the first trimester when organogenesis is occurring. Use of ionizing radiation should be avoided during this period. The teratogenic effects of radiation are summarized in Table 65.5. In addition, ionizing radiation has a potential to induce development of childhood cancers such as leukemia. Historic studies raised concern that *in utero* radiation exposure may increase the incidence of childhood malignancy by 1.3–2 times [31, 34]. However, more recent investigations have reputed this evidence [35]. The National Radiological Radiation Board concluded that the majority of diagnostic radiologic procedures performed in an individual pregnancy presents no substantial risk and carries a less than 1 in 5000 chance of developing a fatal childhood cancer (1 in 33 000 per mGy). Additionally, the risk is less than 1 in 10 000 for development of induced inheritable disease (1 in 40 000 per mGy) [36, 37].

**Table 65.4** Fetal radiation doses for radiologic tests.

| Procedure | Fetal dose (mGy) |
|---|---|
| CT scan (conventional) | 8.0–49 |
| CT scan (limited) | 0.244–1.372 |
| IVU | 1.7–10 |
| KUB | 1.4–4.2 |
| Nuclear renogram (MAG3 or DTPA) | 0.2–4.0 |
| MRI | No radiation, no known adverse effects |
| Ultrasonography | No radiation, no known adverse effects |

CT, computed tomography; IVU, intravenous urography; KUB, kidney–ureter–bladder plain film; MAG3, mercaptoacethyltriglycine; DTPA, diethyltriamine penta-acetic acid; MRI, magnetic resonance imaging.

**Table 65.5** Effects of significant radiation exposure on the fetus.

| Gestational age (weeks) | Radiation effect |
|---|---|
| 2–4 | All lethal or no impact on fetus, without any malformations present |
| 4–10 (organogenesis) | Microcephaly, growth retardation, gross malformations |
| 10–17 (peak neurologic development) | Microcephaly, mental retardation, growth retardation and sterility in adult life |
| 17–40 | Adverse effects seen rarely, if ever |

## Ultrasound

Ultrasonography (Figure 65.1) is the most useful initial test when acute abdominal or flank pain in pregnancy is investigated. The appeal of ultrasound derives from the lack of ionizing radiation and absence of harmful effects, documented over many years of use. Ultrasonography can effectively evaluate the renal parenchyma, pelvicalyceal system, and dilated ureter, and to some extent visualize renal and ureteral calculi.

The accuracy of ultrasonography in the detection of renal calculi is reported to be between 34 and 86% [20–22]. This wide variation in the reported accuracy most likely derives from the fact that ultrasound is operator-dependent. Additionally, ultrasonography is very nonspecific and often

cannot distinguish between hydronephrosis of pregnancy and that secondary to calculi.

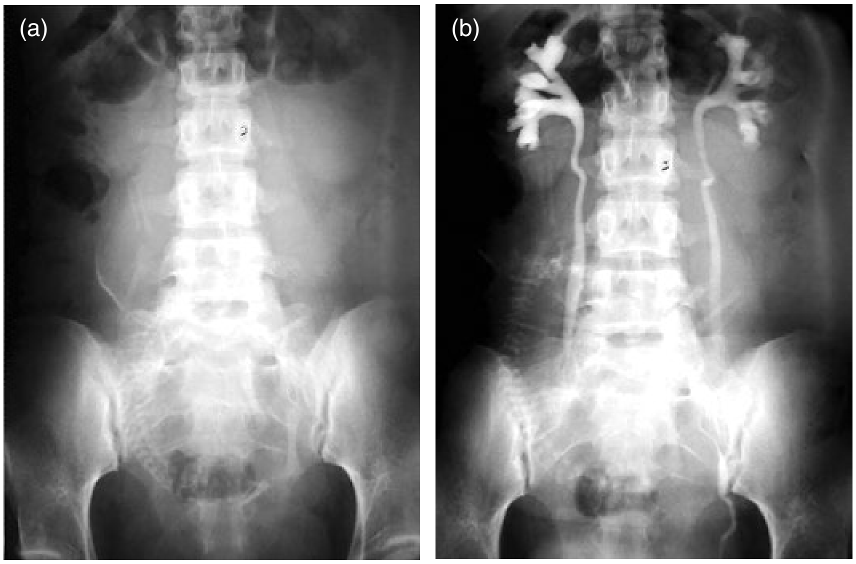
Several modifications to ultrasonography have attempted to improve its accuracy. Transvaginal ultrasound was demonstrated to be effective in the detection of distal ureteral calculi [38]. Detection of hydroureter below the pelvic brim, with any ultrasound approach, may alert the operator to the presence of distal ureteral calculi [39]. The presence of ureteral jets on ultrasound or Doppler ultrasound can exclude complete ureteral obstruction in 80–100% of cases [40].

Resistive index (RI) measurements may increase the accuracy of ultrasonogarphy in distinguishing between the physiologic dilation and calculus-related obstruction [41]. An RI of 0.70 was demonstrated to have 87% accuracy, 45% sensitivity, and 91% specificity for diagnosis [41, 42]. Additionally, a difference in RI values (ΔRI) between the affected side and the normal contralateral kidney of 0.06 increases the sensitivity of ultrasonography to 95%, with specificity of 100% and accuracy of 100% [42]. This type of ultrasonography adjunct was demonstrated to be limited by pre-existing renal disease, nonsteroidal anti-inflammatory drugs (NSAIDs) and acute onset of obstruction (<6 hours).

## Intravenous urography

Intravenous urography (IVU) (Figure 65.2) is effective in describing anatomy and function of the collecting system, along with the site and degree of potential

**Figure 65.2** (a, b) Kidneys, ureters, and bladder intravenous urogram demonstrating a right ureteral calculus in a 30 year-old pregnant woman, G1P0 GA 29 weeks.



obstruction. IVU can be considered as a second-line investigation for hydronephrosis of pregnancy. Small published series report relatively high specificity in diagnosing renal calculi in pregnancy [20, 43]. If needed, a limited three-shot protocol should be used: a scout film, 15–20 minute film, and a selected delayed image at 2 hours. Fetal shielding should be used at all times [44].

IVU, if considered, should be used judiciously due to potential risks of intravenous contrast and fetal radiation exposure. Intravenous contrast was demonstrated to cross the placenta in small quantities, but without any described teratogenic effects [45]. However, exposure to iodinated intravenous contrast during late pregnancy can lead to fetal thyroid suppression, and requires screening for neonatal hypothyroidism [45].

A limited IVU delivers 0.5 mGy of radiation to the fetus, which is below the 5 mGy safety point. Fetal shielding and films obtained in a prone position can further reduce the dose.

## Computed tomography

A traditional computed tomography (CT) scan (Figure 65.3) remains contraindicated in pregnancy due to the high dose of ionizing radiation delivered. Recently, however, a low-dose CT scan protocol has been described for the detection of renal calculi during pregnancy. A low-dose CT scan protocol uses a pitch of 1.5 (from 0.75 in regular CT), 120 kV, and a mean of 109 mA. With these modifications the mean delivered fetal radiation exposure is 705.5 mrad (range 244–1372 mrad), although this is probably an overestimate due to maternal changes in body geometry. Obese patients receive a higher estimated dose on average. The resulting CT images are of much lower quality in comparison to traditional scans, but this investigation still provides high sensitivity and specificity for detection of renal and ureteral calculi.

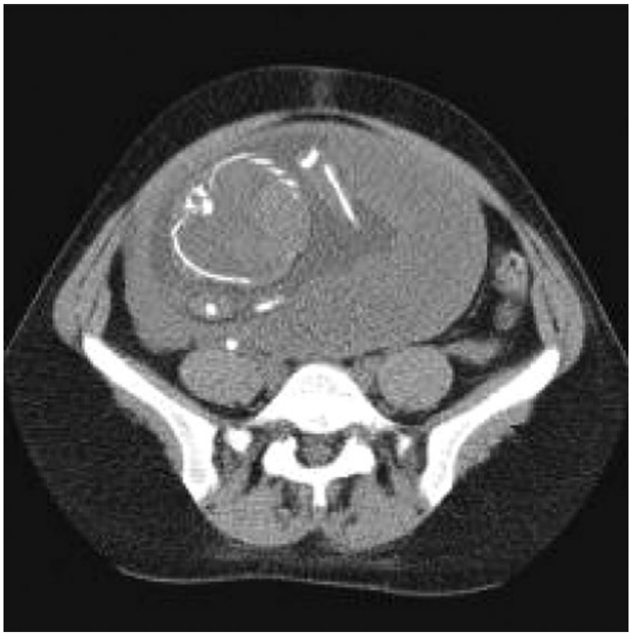


**Figure 65.3** Low-dose CT scan demonstrating a right ureteral calculus in a 29 year-old woman, G1P0 GA 27 weeks. *Source:* [46]. Reproduced with permission of Mary Ann Liebert, Inc.

Based on the finding of a small Research Ethics Board (REB)-approved study, the authors concluded that a low-dose CT scan is more sensitive than ultrasound and improves decision-making [46]. In another recent study, the positive predictive value of low-dose CT scan was the highest (95.8%) compared to renal ultrasound alone (77%) or magnetic resonance imaging (MRI) (80%) in the diagnosis of urolithiasis during pregnancy [47]. The rate of negative ureteroscopies was the lowest in pregnant patients who had low-dose CT scan as part of their preoperative evaluation (only 4.2%) [47]. Thus, the judicious use of low-dose CT scans in pregnant women with flank pain and negative initial ultrasound is advocated

## Magnetic resonance

MRI in pregnancy produces high-quality images of urinary tract anatomy. Heavily weighted T2 MRI pulse sequences or use of intravenous gadolinium can produce precise urograms, comparable to those produced by IVU. The accuracy of MRI in delineating pathologic obstruction from hydronephrosis of pregnancy ranges from 93 to 100% [48]. MRI's diagnostic accuracy can be enhanced by combining it with Doppler ultrasonography and nuclear renography [49]. To date, no harmful effects have been reported with the use of MRI in pregnancy [50]. Experience with gadolinium is limited, but gadolinium-based contrast agents can cross the placenta and remain within the amniotic fluid during pregnancy, raising theoretical concerns over the possible risk of nephrogenic systemic fibrosis [51]. The National Radiological Radiation Board recommends avoiding gadolinium in the first trimester of pregnancy. The main limitation of MRI remains the inability to visualize the stone. The presence of the stone has to be inferred from several soft signs such as "signal voids," "double kink," and perinephric and periureteral edema. Additional limitations include the time-consuming nature of performing MRI (although this continues to improve with new-generation scans), its lower availability, and high costs. Patients afflicted with claustrophobia also will not be able to undergo this diagnostic procedure.

## Management

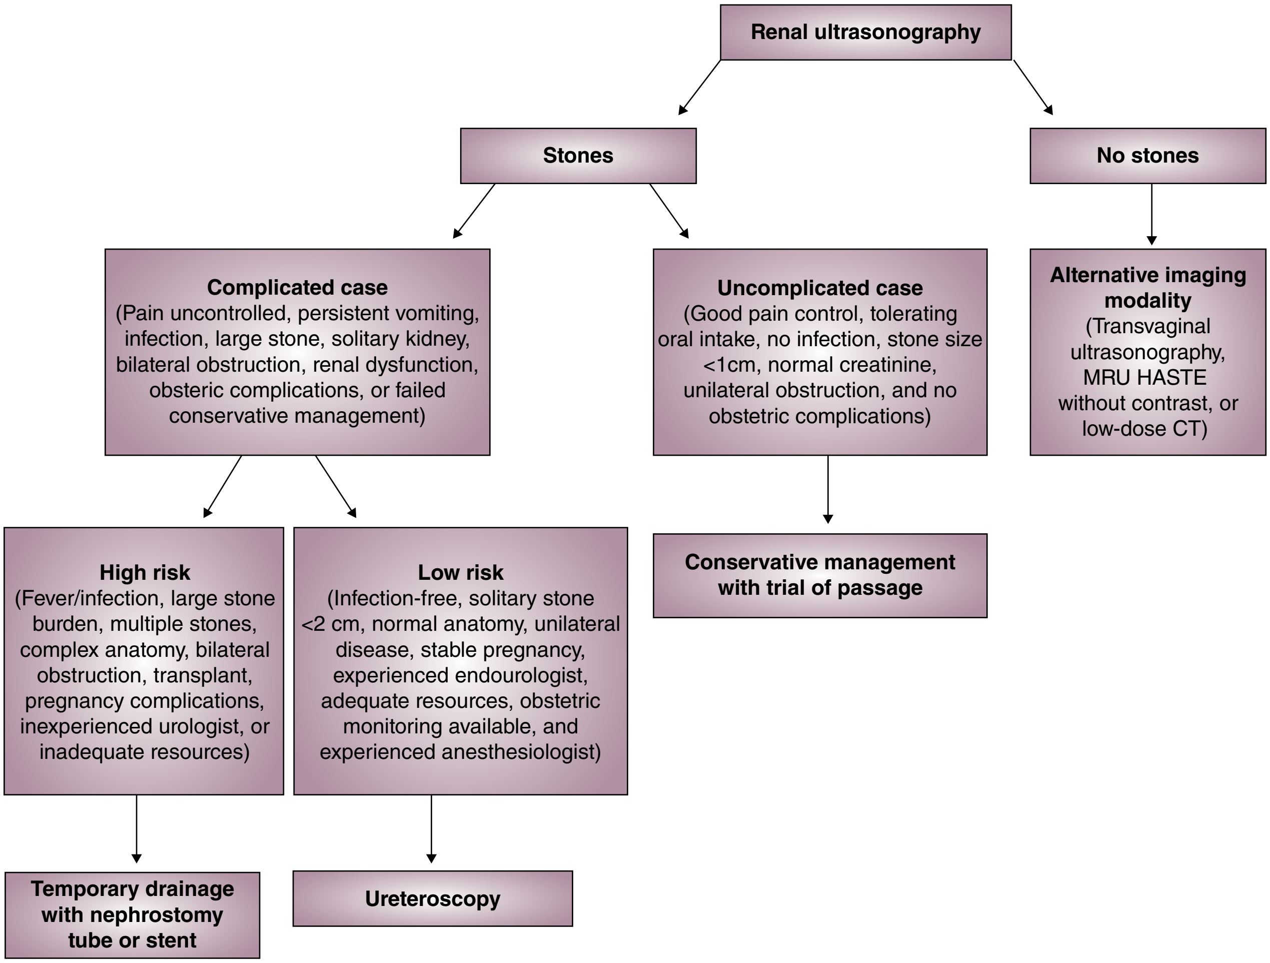
### When to intervene?

Figure 65.4 shows a suggested management plan for urolithiasis during pregnancy. The rate of spontaneous stone passage in pregnancy is between 64 and 84% [20, 24]. Up to 50% of the remaining stones will pass in the postpartum period [20]. Based on these data, the guiding principle of therapy remains that of conservative management. Conservative management requires hydration, antibiotics, antiemetics, analgesics, and close daily follow-up during the symptomatic period. Straining of urine is also advised. Medical expulsive therapy (MET) drugs, including alpha-blockers and calcium-channel inhibitors, are classified as group B drugs during pregnancy [52]. The safety of tamsulosin was examined during pregnancy in a study including 27 pregnant women [53]. It was not associated with any increase in adverse maternal or fetal outcomes; however, two infants in the MET group died of sudden infant death syndrome within 6 months of birth compared to none from the control group [53]. Thus, further studies are needed to determine the long-term safety of MET drugs during and after preganancy.

Conservative management of urolithiasis will fail in approximately 15–30% of pregnant women [54]. Indications for intervention in symptomatic pregnant patients are the same as in the nonpregnant population. These include sepsis, renal failure from obstruction of a solitary kidney or bilateral obstruction, uncontrolled pain, premature onset of labor, preeclampsia, and poor access to expert urologic care.

### Anesthetic risks

Use of anesthesia for nonobstetric surgery during pregnancy has a potential for inducing fetal congenital malformations, spontaneous abortion, and premature labor [55]. Thus, nonemergency surgery during pregnancy



Renal ultrasonography
Stones
No stones
Complicated case (Pain uncontrolled, persistent vomiting, infection, large stone, solitary kidney, bilateral obstruction, renal dysfunction, obsteric complications, or failed conservative management)
Uncomplicated case (Good pain control, tolerating oral intake, no infection, stone size <1cm, normal creatinine, unilateral obstruction, and no obstetric complications)
Alternative imaging modality (Transvaginal ultrasonography, MRU HASTE without contrast, or low-dose CT)
High risk (Fever/infection, large stone burden, multiple stones, complex anatomy, bilateral obstruction, transplant, pregnancy complications, inexperienced urologist, or inadequate resources)
Low risk (Infection-free, solitary stone <2 cm, normal anatomy, unilateral disease, stable pregnancy, experienced endourologist, adequate resources, obstetric monitoring available, and experienced anesthesiologist)
Conservative management with trial of passage
Temporary drainage with nephrostomy tube or stent
Ureteroscopy

**Figure 65.4** Suggested management plan of pregnant patients with urolithiasis. *Source:* [97]. Reproduced with permission of Nature Publishing Group.

should not be performed. Open surgery should be considered only as treatment for septic patients who have failed to respond to any other therapeutic options and when endourologic expertise or equipment is not available [54, 56]. Performing any surgery during the first trimester was found to increase risk of miscarriage [57] and in the third trimester of premature labor [58]. The optimal time for performing nonobstetric surgical intervention during pregnancy is the second trimester [58].

In general, the dosing of both general and locoregional anesthetics during pregnancy is decreased [59, 60]. The increased levels of progesterone and endorphins that have been documented in pregnancy probably play a role in decreasing the minimal alveolar concentrations of the inhalational agents halothane and isofulrane [59], whereas progesterone has also been reported to enhance neuronal membrane sensitivity to local anesthetics [60], thereby diminishing the dose. Drug dosing for spinal and epidural anesthesia was reported to diminish even further in the later stages of pregnancy due to compression of the cerebrospinal space and subsequent epidural venous congestion [61].

Any surgical intervention during pregnancy should involve the obstetric team for monitoring of the fetal heart rate and uterine activity. Fetal monitoring should continue for 24 hours postintervention [62]. NSAIDs should not be used for analgesia as they may induce premature closure of the fetal ductus arteriosus [63].

## Endourologic interventions

### Ureteric stenting

Ureteral stenting represents a temporizing measure, with definitive management deferred until the postpartum period. This approach minimizes or eliminates the requirement for anesthesia, but has several drawbacks. Stent insertion can be accomplished using either fluoroscopy or ultrasound. Fluoroscopy is preferable, but is associated with exposure to ionizing radiation. If using fluoroscopy, fetal shielding and pulsed imaging can reduce radiation exposure. Ultrasound-guided insertion of a ureteric stent eliminates radiation exposure completely [64].

The main drawbacks of ureteric stenting during pregnancy are stent discomfort and stent encrustation. Stent discomfort is similar to that in the nonpregnant population and can manifest as an increase in urinary frequency and urgency, dysuria, mild gross hematuria, and flank pain. Stent discomfort in pregnancy is usually heightened secondary to the presence of overactive bladder symptoms that many women experience in the later stages of pregnancy. The risk of stent encrustation during pregnancy is increased secondary to hypercalciuria and hyperuricosuria of pregnancy. This increased risk necessitates frequent stent exchanges, every 4–6 weeks [21, 65]. The cumulative risks of frequent stent exchanges may exceed that of a single definitive procedure.

### Indications for a percutaneous nephrostomy

A percutaneous nephrostomy (PCN) tube is also a temporizing measure that provides immediate and efficient decompression of the urinary tract. PCN insertion can be achieved with ultrasound guidance and under local anesthesia (usually inserted by an interventional radiologist). The main advantages of this treatment modality are absence of ionizing radiation, minimal anesthesia requirements, avoidance of ureteral manipulation, and very effective drainage of the urinary tract. It also establishes a percutaneous tract for later definitive management of calculi. These attributes often make PCN insertion a preferred option for treatment of septic patients or patients during the first trimester [21, 56].

The main disadvantages of PCN tubes are the risk of bleeding during insertion, bacterial colonization, tube dislodgement, blockage by debris, and tube discomfort. PCN tube blockage, encrustation, and dislodgement necessitate PCN exchanges every 6–8 weeks as a preventative measure.

### Ureteroscopy

At present, ureteroscopy is considered the procedure of choice in the management of symptomatic urolithiasis in pregnancy, following the failure of conservative management. Safe and successful ureteroscopic management requires modern endoscopic equipment and sufficient endourologic expertise.

The safety and effectiveness of ureteroscopy in pregnancy has been demonstrated in a number of small series [66–85] (Table 65.6). A recent meta-analysis of published reports has documented the safety of ureteroscopic stone extraction or intracorporeal lithotripsy in pregnant women to be equal to that in the nonpregnant population, and complication rates have been low (0–20%) [86].

Ureteroscopy can be performed under general or spinal anesthesia. Intravenous sedation with fentanyl and propofol has also been described. The patient is positioned in the modified dorsal lithotomy position [67–69]. Both rigid and flexible ureteroscopes can be used, with instruments sized 8 Fr or smaller, which do not require the dilation of the ureteric orifice [70–72]. Ureteroscopy can be performed either with ultrasound guidance or with pulsed fluoroscopic imaging and mandatory fetal shielding. Performing ureteroscopy in pregnancy is not considered technically difficult, as physiologic dilation of the ureter helps with the manipulation of flexible ureteroscopes [73].

The holmium:YAG laser has emerged as the preferred and safest intracorporeal lithotripter utilized in pregnancy

**Table 65.6** Summary of studies of ureteroscopic management of urolithiasis during pregnancy.

UTI, urinary tract infection.

[74, 75]. The holmium:YAG laser has a wide safety margin due to its unique wavelength (2100 nm) and limited depth of penetration in a fluid environment (<0.5 mm from the tip of the probe). Use of the holmium:YAG laser was reported to result in an 89% overall stone-free rate [74]. A theoretical concern with its use is the production of cyanide during laser lithotripsy of uric acid stones. However, there are no published reports of cyanide toxicity to date [86, 87]. The risk of cyanide toxicity should be negligible, as any cyanide produced during the lithotripsy should be diluted out from the urinary tract with the irrigant.

Alternative intracorporeal lithotripters used in pregnancy include the ballistic or pneumatic lithotripter, ultrasonic lithotripter, and forceps crushers [88–90].

Ultrasonic lithotripsy is known to be very safe to the surrounding tissues [91], but there is a theoretical concern regarding fetal auditory development. However, there is evidence to suggest that the peak pressure of the sound emitted by all intracorporeal lithotripters within the ureter does not affect fetal auditory development [92]. The main limitation of ultrasonic lithotripsy remains the rigid nature of the probe that restricts its use to rigid or semirigid ureteroscopes.

The electrohydraulic lithotripter (EHL) has the lowest margin of safety for use in pregnancy. EHLs generate high peak pressures and the electrical energy generated from the probe poses a potential risk for fetal injury and induction of premature labor. It is not recommended for use in pregnancy [44, 93].

The potential risks of ureteroscopy are similar to those in the nonpregnant population and include urinary tract infection, sepsis, ureteral perforation, and ureteral avulsion. In experienced hands and with use of proper equipment the complication rates are very low (Table 65.6).

### Percutaneous nephrolithotomy

Percutaneous nephrolithotomy (PCNL) is not advised during pregnancy. The necessity of prolonged general anesthetic, prone positioning, and need for fluoroscopy make PCNL a high-risk procedure during pregnancy. Nonetheless, with recent advancements of technique, cases of PCNL during pregnancy were reported to be successful using supine or lateral flank position and performing the procedure under total ultrasound guidance [94, 95].

### Extracorporeal shock-wave lithotripsy

Extracorporeal shock-wave lithotripsy (SWL) is presently contraindicated in pregnancy due to the potential adverse effects of high-energy shock waves on the fetus and the ionizing radiation exposure. However, treatment of six unknowingly pregnant women was not found to result in fetal malformations or chromosomal anomalies in the children [96].

## Conclusions

The safe and effective management of calculi in pregnancy requires a thorough knowledge of anatomic and physiologic changes that occur with each stage of pregnancy. Both fetal and maternal health must be considered. The use of ionizing radiation has to be minimized. Clinicians must use a team approach and adhere to strict indications for intervention in order to maximize a successful outcome for the mother and fetus.

# Management of Renal Colic and Triage in the Emergency Department

*Marius C. Conradie*

*Netcare Waterfall City Hospital, Johannesburg, South Africa*

## Introduction

Acute renal colic is probably the most painful event a person can endure. Renal colic affects approximately 1.2 million people each year and accounts for approximately 1% of all hospital admissions. Most active emergency rooms treat an average of at least one patient with acute renal colic every day, depending on the size of the hospital [1]. Renal colic is often the supposed diagnosis made in the emergency room in patients presenting with an acute onset of flank or loin pain. Often, multiple investigations are done before the diagnosis is confirmed. Frequently this causes a delay in appropriate management. It is up to the attending physician or urologist not only to make a prompt diagnosis but also to initiate effective pain control and identify potentially complicated renal colic.

## Classic presentation of renal colic: symptoms and signs

Patients with acute renal colic classically present with a sudden onset of severe pain originating in the flank. The initial presentation typically lasts 3–18 hours. The progression of pain has been described as having three clinical phases. The typical attack starts slowly and insidiously. The pain typically waxes and wanes in severity, and develops in waves or paroxysms that are related to movement of the stone in the ureter and associated ureteral spasm. Paroxysms of severe pain usually last 20–60 minutes. Pain is thought to occur primarily from urinary obstruction with distension of the renal capsule. The pain reaches its maximum 1–2 hours after the start. In the constant phase, the period of sustained maximal pain, the pain tends to remain constant until it is either treated or allowed to improve spontaneously. Most patients arrive in the emergency room during this phase of the attack. In the final phase of renal colic, relief can occur spontaneously at any time after the initial onset and most commonly lasts 1.5–3 hours.

The pain may localize at different sites of the abdomen depending on the exact position of the calculus in the urinary tract. Stones commonly become impacted in the urinary tract in a calyx, at the ureteropelvic junction, at the pelvic brim where the ureter begins to arch over the iliac vessels, at the broad ligament in females, and at the ureterovesical junction, which is the most common site of impaction. Pain from upper ureteral calculi tends to radiate to the flank and lumbar areas. Mid-ureteral calculi cause pain that radiates anteriorly and caudally. Distal ureteral calculi cause pain that tends to radiate into the groin or testicle in the male or labia majora in the female. If a calculus is lodged in the distal intramural part of the ureter, symptoms may mimic detrusor overactivity or cystitis. These symptoms include suprapubic pain, urinary frequency, urgency, dysuria, or pain at the tip of the penis in men.

On examination of the abdomen, the pain localizes to the costovertebral angle. The remaining examination findings are often unremarkable. The characteristic difference between patients with renal colic and those with an acute abdomen lies in the restlessness of patients with renal colic. Patients with an acute abdomen of surgical origin usually lie as still as possible. Rebound tenderness will be present in an abdomen with peritonitis. The pain is generally diffuse in an acute abdomen as opposed to renal colic where the patient can often point to the site of maximum tenderness, which is likely to be the site of the ureteral obstruction.

Hematuria is often associated with renal colic. However, 15% of all patients with urinary calculi do not have hematuria [2]. Therefore, the lack of hematuria does not exclude the possibility of acute renal colic. Other clinical signs that may be encountered are fever, chills, nausea, vomiting, and tachycardia. The presence of pyuria, fever, leukocytosis, or bacteriuria suggests the possibility of a urinary infection and the potential for an infected obstructed kidney. This is a potentially life-threatening situation and should be treated as a surgical emergency.

## Mechanism of renal colic

Renal colic is the consequence of the acute dilation of the urinary tract proximal to an obstruction along with smooth muscle spasm at the site of the obstruction. High intrarenal pressure promotes local synthesis and release of prostaglandin E2 with subsequent vasodilation of the afferent arterioles, which promotes diuresis and a further rise in renal–pelvic pressure, potentially exacerbating the patient's pain. In addition, ureteral smooth muscle spasm is directly stimulated by prostaglandin E2 [3]. Most of the pain receptors of the upper urinary tract responsible for the perception of renal colic are located submucosally in the renal pelvis, calyces, renal capsule, and upper ureter. Acute distension seems to be most important in the development of the pain of acute renal colic. Muscle spasm, increased proximal peristalsis, and local inflammation at the site of obstruction may contribute to the development of pain through chemoreceptor activation and stretching of submucosal free nerve endings. Renal colic pain rarely, if ever, occurs without obstruction.

### Autoregulatory process associated with obstruction

The initial renal response to acute unilateral ureteral obstruction is the release of prostaglandins, especially E2, resulting in vasodilatation of the afferent arterioles and worsening of ureteral smooth muscle spasm. Subsequently, the dilation of the afferent arterioles results in an increase in renal blood flow and glomerular filtration rate [4]. As a consequence, more urine is produced, and the renal pelvis and ureter dilate further. Distension of the renal pelvis initially stimulates ureteral hyperperistalsis. Peak hydrostatic renal pelvis pressure is attained within 2–5 hours after a complete obstruction. The initial phase of obstruction lasts approximately 1.5 hours and is followed by vasoconstriction of the efferent arterioles with a resultant decrease in renal blood flow. Eventually, the afferent arterioles constrict and ureteral pressures fall [4]. By this time, intraureteral pressures have returned to normal, but the proximal ureteral dilation remains and ureteral peristalsis is minimal. The interstitial edema of the ipsilateral kidney enhances fluid reabsorption, which helps to increase the renal lymphatic drainage to establish a new, relatively stable, equilibrium. At the same time, renal blood flow increases in the contralateral kidney as renal function decreases in the obstructed kidney. The return of renal function after a period of complete unilateral ureteral obstruction is an important clinical concern for the urologist. The renal function recovery rate after 1 week of ureteral obstruction is 100%, but after 4 weeks only a 30% recovery can be expected [5]. If only a partial obstruction is present, the same changes occur, but to a lesser degree.

## Diagnosis

The diagnosis of renal colic is often made based on clinical symptoms alone, although confirmatory tests are usually performed. Additional tests are useful not only to confirm the diagnosis but also to facilitate in the decision-making process on further treatment. Before a decision on treatment can be made, a urologist must know the size, shape, orientation, radiolucency, and location of the stone. Other factors that may influence further treatment are kidney function and the presence of infection, as well as all other clinical information and comorbid conditions the patient may have.

### Laboratory investigations

#### Urinalysis

Patient history, physical examination, and urinalysis alone cannot help confirm or exclude urolithiasis with sufficient accuracy. In particular, hematuria testing has a sensitivity of 81–84% and a specificity and negative predictive value of 48 and 65%, respectively [6, 7].

In addition to the presence of blood in the urine, the presence or absence of leukocytes, crystals, and bacteria, and the urinary pH should be documented. A urinary tract infection should be suspected if the number of white blood cells (WBCs) in the urine is greater than 10 per high-power field. Determining urinary pH may be helpful in planning treatment. With a pH lower than 6.0, a uric acid stone should be considered. The observation of cystine, uric acid, struvite, or calcium oxalate crystals in the urine may be an indication of the type of calculus ultimately found.

#### Hematologic tests

While mild leukocytosis often accompanies a renal colic attack, a high index of suspicion for a possible infection should accompany any serum WBC count of 15 000/μl or higher in a patient presenting with an apparent acute kidney stone attack, even if afebrile. Urea, creatinine, and electrolyte testing may be helpful in identifying patients with renal function impairment as well as in giving some information on the hydration status of the patient, which may determine their further management.

## Imaging studies

### Plain abdominal radiograph

The historical cornerstone of the evaluation of renal colic was a radiograph of the kidneys–ureters–bladder (KUB). Not all urinary calculi will be visible on the KUB radiograph because of their small size, calculus radiolucency, or overlying bowel gas. Typically, 90% of calculi are radiopaque. However, many calcifications that can be observed on the KUB radiograph are not calculi, but phleboliths, vascular calcifications, calcified lymph nodes, or bowel contents. Typically the differentiation between a phlebolith and a urinary calculus becomes easier when the KUB radiograph demonstrates a lucent center, identifying the calcification as a phlebolith. However, this central lucency is not observed as often on computed tomography (CT) scans. The KUB radiograph is also quite accurate for helping determine the size and shape of a visible radiopaque calculus. It uses the same orientation and anatomic presentation that is observed on fluoroscopy images during endoscopic ureteral surgery. Also, the progress of the stone can be easily monitored with a follow-up radiograph. For these reasons, many urologists recommend a KUB in addition to a CT scan in the workup of renal colic (Figure 66.1).

### Renal ultrasound

Renal ultrasound is most useful in diagnosing relatively large calculi within the renal pelvis or kidney. However, it is less useful than other modalities for detecting ureteral calculi. One benefit is that it can easily diagnose any significant hydronephrosis. Ultrasound can also be used to diagnose other pathologic conditions such as abdominal aortic aneurysm or cholelithiasis, which can sometimes be mistaken for acute renal colic. Combining a renal ultrasound with a KUB radiograph can be adopted as a reasonable alternative when a CT scan cannot be performed.

### Intravenous urogram

Intravenous urography (IVU) has been the imaging modality of choice for investigating acute renal colic since Osborne et al. first described it in 1923 [8]. It provides detailed information about the anatomy of the renal collecting system and ureters, offers some information about renal function and the degree of obstruction, and is good for the planning of calculus surgery (Figure 66.2). When a patient has multiple pelvic calcifications, identifying the actual stone is simple with an IVU and it can also show nonopaque calculi as filling defects.

There are, however, limitations: adequate bowel preparation is necessary for good-quality studies, and there is a risk of contrast-related allergic and anaphylactic reactions (10 and 1% of patients, respectively) [9]. Also, in patients with renal failure and diabetes mellitus, the risk of contrast-induced nephrotoxicity is 25% [10]. A serum creatinine level of more than 2 mg/ml is a relative contraindication to the use of intravenous contrast. Furthermore, there may be a need for delayed films if

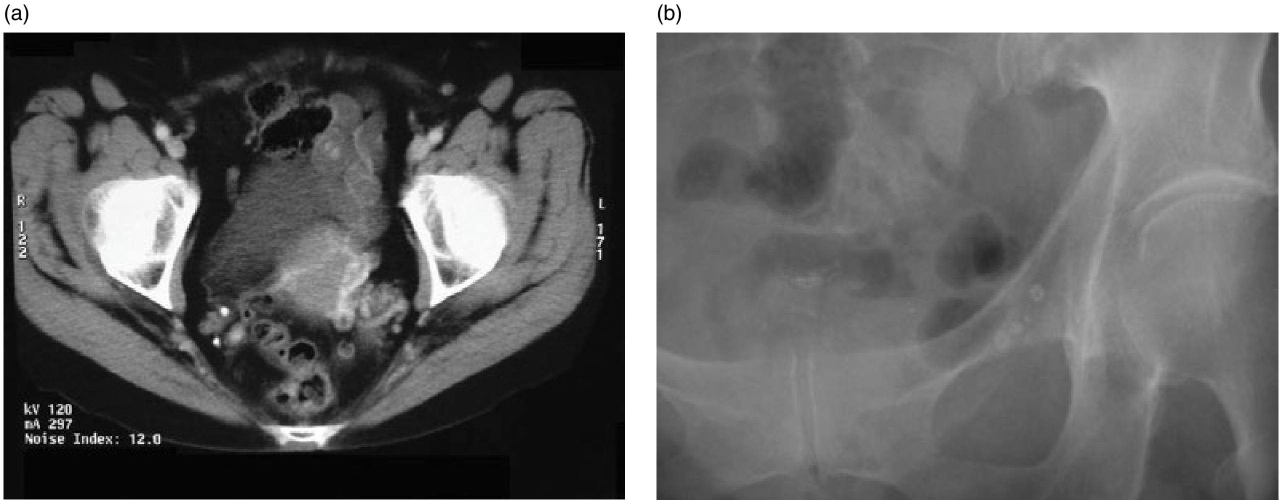

**Figure 66.1** (a) Distinguishing renal calculi from phleboliths in the pelvis can be intricate. This axial noncontrast CT demonstrates two phleboliths in the pelvis. One demonstrates the comet-tail sign, which is a soft-tissue attenuation leading to the phlebolith and represents a vein in which it is located. (b) On a KUB radiograph, a phlebolith classically demonstrates a central lucency whereas ureteral calculi do not.

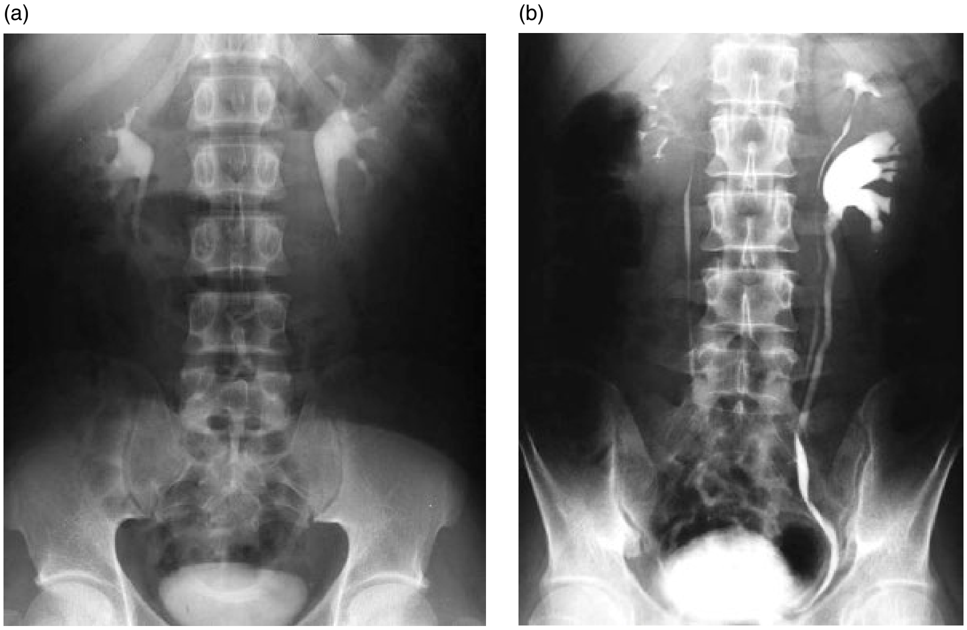

**Figure 66.2** (a) An IVU obtained in a patient with renal colic demonstrates a calculus <6 mm, normal anatomy, and no signs of obstruction, which makes for the ideal candidate for conservative management or medical expulsive therapy. (b) IVU image demonstrates a calculus >6 mm at the ureteropelvic junction in the lower moiety of a kidney with complete ureteral duplication. This represents a clear indication for a surgical intervention.

there is high-grade obstruction, which can lead to delays in diagnosis and treatment.

The classic finding of acute ureteral obstruction is a persistent nephrogram, caused by an increase in the intrarenal concentration of the contrast. Even without observing any specific calculus, the presence of a persistent nephrogram in one kidney with prompt contrast excretion by the contralateral kidney is highly suggestive of ureteral obstruction secondary to a calculus. There may also be columnization on the delayed films. Extravasation of contrast around the collecting system may be a sign of a ruptured fornix, while pyelolymphatic backflow indicates that contrast has entered into the renal lymphatic drainage system. Both are considered signs of a more severe ureteric obstruction.

### Computed tomography scan

The use of a noncontrast helical CT (NCCT) scan to assess patients with acute flank pain was first reported in 1995 by Smith et al. [11]. Recent studies have shown that NCCT is more accurate and reliable than IVU in making a diagnosis in patients presenting with acute flank pain. NCCT has both sensitivity and specificity of 94–100% compared with 60–94% for IVU, partly because NCCT clearly demonstrates both radiopaque and radiolucent stones, as well as detecting alternative causes for a patient's symptoms [12, 13]. Unrelated pathology may be detected by NCCT in 28% of patients [14]. Moreover, NCCT does not require special preparation or intravenous contrast, thus avoiding the risk of contrast-associated reactions and allowing imaging studies to be completed in a few seconds, which improves image quality by reducing respiratory motion and artifact [15, 16]. For these reasons, NCCT has displaced IVU to become the investigation of choice for acute flank pain in many institutions across North America, Europe, and Australasia [13, 17, 18].

Very finely spaced scans are taken through the kidneys and bladder areas, where symptomatic calculi are most likely to be encountered (Figure 66.3). A KUB radiograph is sometimes automatically included in a renal colic study, as mentioned.

Katz et al. found that CT scan estimates of stone size to be similar to those determined by plain film radiography [19]. Both the estimated mean stone diameter and the length were similar on CT and KUB. The limitation of this method is that if CT collimation is too large relative to the stone, the entire stone may not be scanned, leading to underestimation of stone length. This inaccuracy can be best compensated for by making sure that slices are small in relation to stone size. Therefore, 5 mm collimation is preferred to 10 mm collimation. In addition to verifying similarity of stone size estimates by CT and KUB, Katz et al. also found that the prediction of spontaneous stone passage was similar using the two imaging modalities. It is widely believed that transverse stone dimension is more important than length in predicting the likelihood of spontaneous passage. Interestingly, the

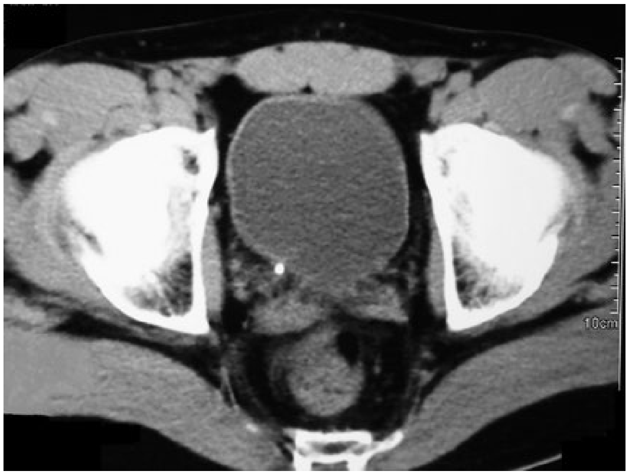

**Figure 66.3** Classic example of a calculus <6 mm in the intramural part of the ureter. Conservative management or medical expulsive therapy would be an appropriate course of action.

study demonstrated the measured anteroposterior stone diameter on CT to be wider in many cases than the measured transverse diameter on CT and plain film. This result could be explained by orthogonal imaging in curved portions of the ureter, where larger anteroposterior diameters were found irrespective of stone location. At any given point along the CT scan, the ureter is either ascending or descending; therefore, an anteroposterior cut would slice tangentially, and cause a wider anteroposterior than transverse diameter.

Phleboliths are often confused with ureteral calculi. On a KUB radiograph, the characteristic lucent center of a phlebolith is often visible, but is not present in a true calculus. Unfortunately, as mentioned above, CT scans usually fail to reveal this central lucency. The "rim sign," originally reported by Smith et al. in 1995, is described as a rim or halo of soft tissue, visible on CT scans, that completely surrounds ureteral calculi [11]. This effect is enhanced by the local inflammation in the ureteral wall with subsequent edema at the site of the calculus. The rim sign is generally incomplete with phleboliths. The rim sign is more likely to be present in small stones up to 5 mm in diameter.

Calculi, including relatively radiolucent uric acid calculi, and cystine and matrix stones, are easily identifiable on CT scan. While they do not contain calcium, they are still much denser than the surrounding soft tissue. The only exception is indinavir calculi, which are not visible on CT scans. These patients require an IVU that will demonstrate a filling defect.

Currently, CT scans can be used to estimate the relative density of the calculus and composition to some extent. The mean peak Hounsfield reading of uric acid calculi and calcium oxalate calculi are around 344 ± 152 and 652 ± 490 HU, respectively [20].

Secondary signs of obstruction may be visible on CT scans. In some cases, if the stone passed shortly before the study, these signs may be the only evidence that the patient had a stone. These secondary signs include ureteral dilation with hydronephrosis and renal enlargement with streaking of the perinephric fatty tissue [2]. Although NCCT is unable to provide direct information on function and drainage, the degree of obstruction can be assessed by secondary signs, such as the severity of hydronephrosis and ureteral dilation and the presence of perinephric fluid, indicating forniceal rupture. Smith et al. found a high correlation between secondary signs of obstruction and the presence of a ureteral calculus. In particular, the combination of collecting system dilation and perinephric stranding had a positive predictive value of 98%, while the absence of both of these secondary signs had a negative predictive value of 91% [21].

The biggest advantage of a CT scan over an IVU lies in its ability to diagnose other underlying pathology mistaken for renal colic, such as aortic aneurysms, pancreatitis, appendicitis, ovarian problems, and bowel disorders.

Disadvantages of a CT scan include difficulties in identifying a stone if the patient exhibits limited hydronephrosis with additional pelvic calcifications and the little information it gives on the renal function. Stone location can be described in anatomic terms, but the scan lacks the surgical orientation that most urologists prefer. Spiral CT scans can, however, allow for anatomic three-dimensional image reconstruction, which may be useful in the evaluation and pretreatment planning (Figure 66.4).

It is recommended to add a KUB radiograph when a renal colic CT scan study is performed for acute flank pain, especially when the CT scan findings are positive for urolithiasis. The KUB radiograph not only provides more precise information about the size and shape of a stone, but it also quickly reveals whether stones are radiopaque or radiolucent. Follow-up evaluations are easier because only a repeat KUB radiograph is needed for comparison.

## Differential diagnoses of renal colic

### Alternative urologic pathology

**Pyelonephritis**

Pyelonephritis is a common cause of flank pain, but the discomfort is usually described as a relatively mild dull ache rather than typical renal colic pain. Fever, chills, nausea, and vomiting are often associated symptoms. Flank and costovertebral angle tenderness are also present, but more severe than with renal colic.

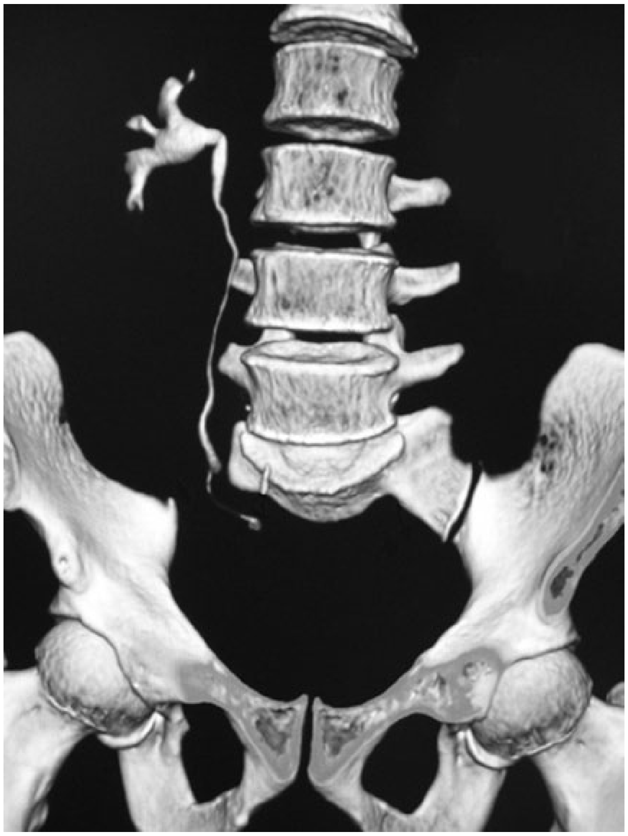

Figure 66.4 A three-dimensional reconstruction of NCCT of a patient with a single kidney with a calculus impacted at the pelvic brim. This imaging option can be a valuable adjunct in high-risk patients in choosing the most appropriate treatment option as well as planning the surgery.

**Renal abscesses**

Renal abscesses tend to cause pain similar to pyelonephritis rather than renal colic. Sometimes, a flank mass may be palpable. Urinalysis often demonstrates a urinary infection, but can be normal in some cases. Fever and chills are common. It is usually associated with patients who are immune compromised.

**Kidney tumors**

Kidney tumors may cause flank pain either from renal capsular stretching or by mechanical compression of large tumors. Primary tumor extension into the renal pelvis can cause urinary obstruction, although this is usually a slow process during which patients are often asymptomatic.

**Ureteropelvic junction obstruction**

Ureteropelvic junction obstruction is one of the more common causes of renal pain. The pain is similar to an acute ureteral obstruction and usually follows the intake of large amounts of fluid, which causes diuresis resulting in renal pelvic distension and colic. The pain is not as severe as renal colic and is recurrent in nature.

**Obstructive uropathy due to other causes**

Other obstructive causes include:

- blood clots
- renal papillary necrosis
- ureteral strictures
- renal cysts
- polycystic kidney disease
- pyelocalyceal diverticulum.

### Vascular pathology

**Abdominal aortic aneurysms**

Patients with an abdominal aortic aneurysm may present with symptoms of flank pain that mimic renal colic. Symptoms are generated from either a leaking or ruptured aneurysm. Large aneurysms may lie in close approximation to the ureter and cause hematuria from local ureteral inflammation. Abdominal aortic aneurysms are best diagnosed with ultrasound or a CT scan. CT scanning is particularly useful in cases of suspected renal colic in patients older than 50 years who are at risk for an aortic aneurysm.

### Gastrointestinal tract pathology

Causes include Crohn's disease, diverticulitis, appendicitis, cholecystitis, and pancreatitis.

### Gynecologic pathology

Causes include ectopic or tubal pregnancy, endometriosis, ovarian cyst, and pelvic inflammatory disease.

## Medical and surgical treatment

The management of acute renal colic is a problem commonly encountered by both urologists and emergency medicine physicians. One aspect of the medical treatment is the management of acute renal colic pain, a condition that demands rapid and effective analgesia. Currently, nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids are the best agents for acute renal colic, overshadowing other drugs such as antimuscarinics (i.e. hyoscine butylbromide) [22].

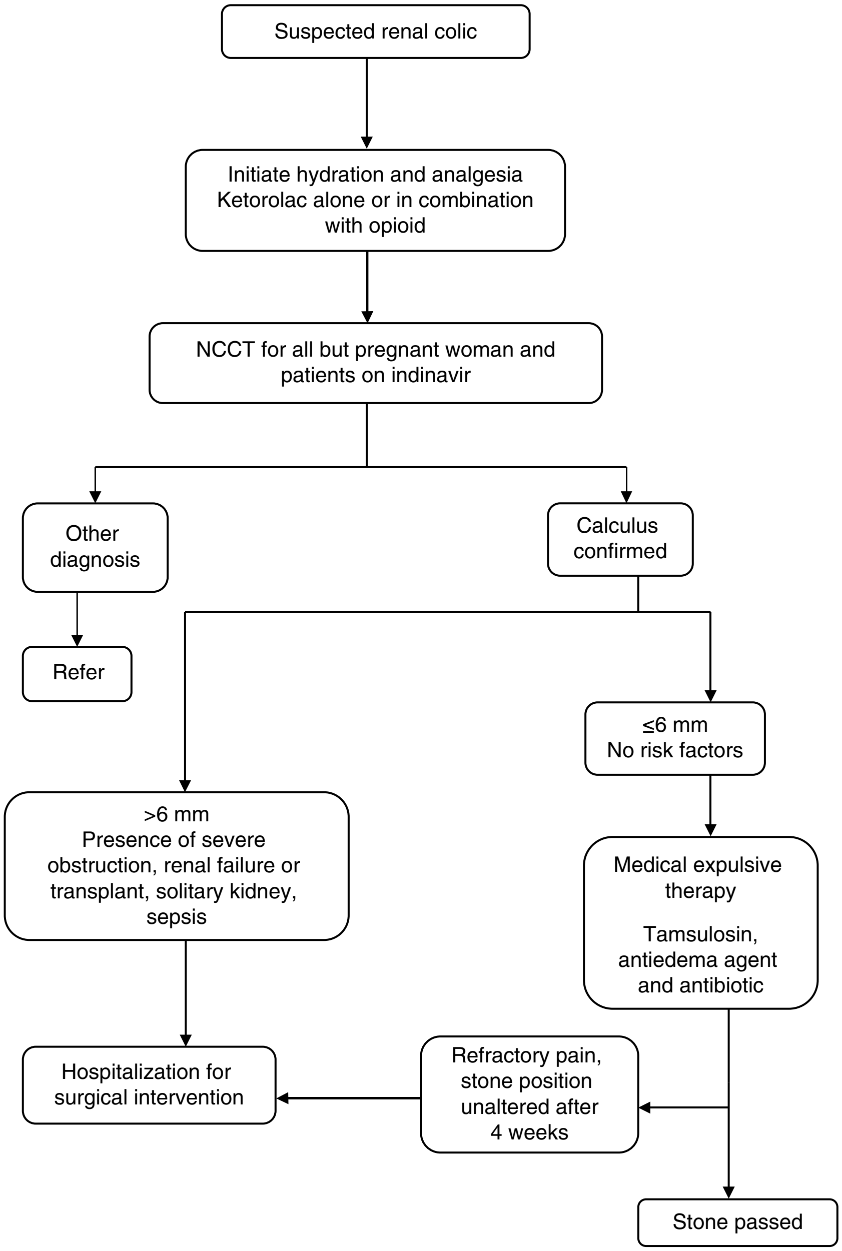
In addition to controlling the pain associated with obstructing calculi, drug therapy that promotes the expulsion of stones is an evolving aspect of medical therapy.

Observation with analgesia is most appropriate for patients without infection whose pain can be well-controlled with oral medications. Key factors contributing to stone retention include edema, ureteral spasm, and infection, all of which are potential pharmacologic targets. However, in cases of persistence, ureteral obstruction, or pain, other minimally invasive interventions are preferred [23].

Figure 66.5 shows an algorithm for the evaluation, triage, and further management of suspected renal colic.

## Triage

The majority of emergency departments (EDs) in the United States (87.4%) do not have guidelines regarding the treatment of patients who present with renal colic [1]. Having well-designed guidelines in the ED will not only facilitate and expedite diagnosis and enable appropriate treatment, but will also significantly decrease patient morbidity and channel patients with life-threatening conditions to the appropriate departments without delay. Such guidelines should help



Suspected renal colic
Initiate hydration and analgesia Ketorolac alone or in combination with opioid
NCCT for all but pregnant woman and patients on indinavir
Other diagnosis
Calculus confirmed
Refer
≤6 mm No risk factors
>6 mm Presence of severe obstruction, renal failure or transplant, solitary kidney, sepsis
Medical expulsive therapy
Tamsulosin, antiedema agent and antibiotic
Hospitalization for surgical intervention
Refractory pain, stone position unaltered after 4 weeks
Stone passed

**Figure 66.5** Algorithm of the evaluation, triage, and further management of a patient with suspected renal colic.

acquire the most suitable imaging modalities, decide which patients should be hospitalized or referred to other departments, and facilitate in the triage and decision-making on conservative versus surgical therapy.

### Predicting spontaneous stone passage

Setting patient expectations with regard to the likelihood of spontaneous stone passage and the time to stone passage is critical to help guide the patient to make an informed decision between conservative management and surgical intervention. The management of patients with ureteral calculi relies on estimated stone size and the stone's potential for spontaneous passage. Several factors influence the likelihood of spontaneous stone passage, such as location and history of spontaneous expulsion. Indeed, with accurate information, more patients might select early intervention as opposed to expectant observation. In general, smaller calculi are more likely to pass spontaneously, but stone passage also depends on the specific anatomy of the upper urinary tract. Any anatomic abnormality could make the passing of even a small stone impossible.

Spontaneous passage of urinary calculi of less than 5 mm in diameter may occur in most patients, although the calculus may take 40 days or more to pass [24]. Prospective clinical trials have stratified the spontaneous stone passage rate and time to stone passage. Stones of 4 mm and smaller have a 94% chance of spontaneous passage, whereas stones of 4–6 mm in size will pass spontaneously 50% of the time. Average time to stone passage was 1 week for a stone of less than 2 mm, 2 weeks for a stone of 2–4 mm, and 3 weeks for a stone of 4–6 mm. Calculi of greater than 6 mm are unlikely to pass spontaneously [25–28].

Excluding complications related to stone disease, such as severe hydronephrosis, renal insufficiency, intractable pain, and infection, that mandate a more aggressive approach (ureteral stent, nephrostomy, retrograde intrarenal surgery, extracorporeal shock-wave lithotripsy), drug therapy is useful in the management of urolithiasis and represents an important adjunct to conservative therapy.

With regard to cost, observation represents the most cost-effective approach to ureteral calculi, but it remains unsatisfactory for recurrent stone-formers, in whom the high rate of recurrence precludes a conservative approach [29]. A cost-effectiveness model revealed that a conservative approach to ureteral stones is associated with lower cost than any invasive procedures only if it is followed by stone expulsion [30].

It is suggested that a conservative approach to larger ureteral stones should not be extended for longer than 2 weeks in order to avoid renal function impairment, urosepsis, and intractable pain [31]. Many urologists have adopted the conservative treatment plan of 4 weeks proposed by Hubner et al. [28]. This is safe if the stone is 6 mm or smaller in the absence of severe hydronephrosis.

### Hospitalization

The decision to hospitalize a patient with a stone is usually made based on clinical grounds rather than on any specific finding on a radiograph. Watchful waiting for spontaneous stone passage is certainly the least invasive management option; however, several signs and symptoms may prohibit such a course of action. Fever, chills, or other sign of infection are the most urgent scenarios prohibiting watchful waiting. Evidence of renal insufficiency or frank anuria similarly necessitates urgent intervention. Poorly controlled renal colic pain and vomiting are more subjective indications. Other than extreme cases necessitating inpatient management, clinical scenarios that may warrant acute intervention include inability to perform routine activities safely and reliably, upcoming travel plans, job restrictions, etc. [32]. Patients with obstructing ureteric stones of greater than 6 mm are seldom likely to pass their stone spontaneously, and early admission for procedural therapy may be prudent [2]. Most patients with acute renal colic can be treated on an ambulatory basis. Hospitalization for an acute renal colic attack rarely lasts for longer than 24 hours, after which the patient can go home.

### Surgical intervention

The presence of urosepsis in a patient with an obstruction from stone disease is a true surgical emergency. This condition requires hospital admission with intravenous fluids, antibiotics, and, most importantly, early drainage of the affected kidney using either retrograde-placed double-J stents or percutaneous nephrostomy.

Retrograde endoscopy should be reserved for relatively mild cases that are medically stable. Double-J stents virtually guarantee drainage of urine from the kidney and bypass the obstruction. This relieves patients of their renal colic pain even if the actual stone remains.

In patients with pyonephrosis in association with an obstructing calculus, retrograde endourologic procedures, such as retrograde pyelograms and double-J stent placement, may worsen the infection by pushing infected urinary material into the obstructed kidney and may exacerbate the systemic sepsis. These situations clearly indicate the need for a percutaneous nephrostomy, especially in patients who are hemodynamically unstable. Later, when the infection is under control and the patient is no longer septic, a more definitive procedure can be performed to remove or fragment the obstructing stone.

Approximately 10–20% of all kidney stones may cause the patient enough problems to require surgical removal.

If there is no evidence of movement or passage of a ureteral stone that has been treated conservatively for 3–4 weeks or if pain is intractable, surgical intervention is warranted. Other conditions that may require a more expedited approach are the presence of unusually large stones, high-risk medical conditions, uncontrollable pain, renal failure, solitary kidneys, renal transplants, and pregnancy.

## Hydration

Initial treatment of a renal colic patient in the ED starts with obtaining intravenous access to allow fluid, analgesic, and antiemetic medications to be administered. Some patients may be dehydrated from nausea and vomiting. Some believe hydration may increase the speed of passage of a stone through the urinary tract. Traditionally, patients were aggressively hydrated intravenously or were told to increase their oral hydration to promote stone passage [33]. This practice stems from the thought that the stone might pass spontaneously if forced hydration is utilized. Using hydration as a therapy to assist stone passage remains controversial.

Some urologists worry that the extra fluid only increases the hydrostatic fluid pressure inside the blocked renal unit, exacerbating the pain. In addition to this, diuresis may be detrimental to the ipsilateral renal unit by potentially causing forniceal rupture [34, 35]. Therefore, fluid restriction may be more advantageous to the patient.

Maintenance intravenous fluids are as efficacious as forced hydration with regard to patient pain perception and narcotic use. Moreover, it appears the state of hydration has little impact on stone passage [36].

Intravenous hydration during an episode of renal colic is necessary in patients who are unable to tolerate liquids by mouth. It is therefore recommended that patients who have been vomiting or have laboratory values suggesting dehydration receive appropriate replacement fluids plus their normal maintenance requirements.

## Pain relief

The two principal classes of drugs used for analgesia in renal colic are NSAIDs and opioids. The combination of these drugs is currently the preferred treatment of renal colic at most EDs.

### Narcotics and opioids

The mainstay of medical therapy for patients with acute renal colic is parenteral narcotic analgesics. These medications work primarily on the central nervous system (CNS) to reduce the perception of pain. When considering a medication and dosage range, it must be remembered that acute renal colic is probably the most painful episode to affect humans. Morphine, meperidine, and tramadol are the most commonly used drugs.

Morphine is the principal opium alkaloid product. As a potent narcotic analgesic, morphine sulfate controls severe pain primarily through a CNS mechanism. Adverse effects include respiratory depression, drowsiness, nausea, and vomiting. The usual dose of morphine sulfate is 10 mg/70 kg of body weight intramuscularly every 4 hours. For more rapid results, morphine sulfate can be administered intravenously in doses of 4–10 mg, but it must be administered slowly to avoid excessive adverse effects and respiratory depression.

Similar to morphine sulfate, meperidine is a potent parenteral narcotic analgesic. Doses of 1 mg/kg should be adequate to bring relief to a patient with renal colic. Meperidine offers a slightly more rapid onset of action and slightly shorter duration of analgesic activity than morphine sulfate. The dosage is usually 1 mg/kg intramuscularly every 4 hours. This dosage is reduced by at least 50% when administered intravenously. The actual effective dosage varies according to the source of the pain and the individual's tolerance. As with morphine sulfate, intravenous administration should be performed slowly.

Tramadol is a synthetic cyclohexanol derivative used since the late 1970s. It is a centrally acting analgesic with inhibition of serotonin and norepinephrine reuptake. Fewer side effects are seen with tramadol, although it is less effective for severe pain [37]. Negligible cardiac and respiratory depression has been shown, and reported side effects are minor: mainly nausea and emesis, usually preventable by slow injection of the drug and prophylactic administration of an antiemetic.

For long-lasting pain relief, intravenous opioids titrated to effect are recommended. However, on-demand intravenous titration of drugs is difficult to organize in a busy ED, especially if patients have to leave for the medical imaging department. A continuous intravenous tramadol drip, on the other hand, proved to offer superior analgesia and greater patient satisfaction without an increase in reported side effects [37].

### Nonsteroidal anti-inflammatory drug therapy

NSAIDs have a direct action on the underlying cause of the pain by inhibiting prostaglandin synthesis, and subsequently reduce vasodilatation with a drop in intrarenal pressure, inhibit ureteral smooth muscle contraction, and reduce urinary tract inflammation [38].

There are various NSAIDs available for either intramuscular or intravenous use. The most common intravenous NSAID used in the USA is ketorolac, which works at the peripheral site of pain production rather than on the CNS. It has fewer adverse effects and often provides dramatic improvement in pain symptoms. The dosage is an initial 30–60 mg intramuscularly or 30 mg intravenously, followed by 30 mg intravenously or intramuscularly every 6–8 hours. Ketorolac has been shown to be as effective in the treatment of renal colic as the narcotic meperidine [39, 40].

In more severe cases, ketorolac can be combined with narcotic analgesia with better analgesic effect than either one administered individually. Once the acute episode has been dealt with, an oral NSAID can be used. Of the various enteral NSAIDs, ketorolac, ibuprofen, or the newer oral cyclo-oxygenase-2 inhibitors are equally effective for pain management in outpatients. Chemically, ketorolac and ibuprofen are similar to aspirin and may increase the prothrombin time when administered with anticoagulants. They should be avoided in patients with peptic ulcer disease, renal failure, or recent gastrointestinal bleeding.

#### Antidiuretics

Desmopressin (DDAVP), a potent antidiuretic medication that is essentially an antidiuretic hormone, can dramatically reduce the pain of acute renal colic in many patients. It is thought to work by reducing the intraureteral pressure, but it may also have some direct relaxing effect on the ureteral musculature. Whether this therapy significantly affects eventual stone passage is unknown [41]. It is available as a nasal spray (usual dose 40 μg) and as an intravenous injection (4 μg/ml). Generally, only one dose is administered. While some human studies lack adequate controls and further studies must be conducted, desmopressin therapy currently appears to be a promising alternative to analgesic medications in patients in whom narcotics cannot be used or in whom the pain is unusually resistant to standard medical treatment.

### Antiemetics

Because nausea and vomiting frequently accompany acute renal colic, antiemetics often play a role in renal colic therapy. Metoclopramide is a well-known agent in the treatment of renal colic. Its antiemetic effect stems from its dopaminergic receptor blockage in the CNS. The effect after intravenous injection of 10 mg is rapid; within 3 minutes the patient experiences relief. Other medications commonly used as antiemetics include promethazine and prochlorperazine. Antiemetics are recommended when patients with renal colic have been vomiting actively or report nausea sufficient to interfere with oral therapy.

### Medical expulsive therapy

As discussed above, stone size affects expulsion times, but other factors such as stone shape and edema around the stone may also have an effect. Additionally, the sympathetic nervous system modulates ureteral activity, as demonstrated by the presence of adrenergic receptors in the ureter. Various medications or combinations thereof have been used to facilitate and expedite the passage of ureteral stones. The rationale for the combination of an anti-inflammatory drug (NSAID or steroid) with a smooth muscle relaxant (nifedipine or tamsulosin) is that the former will reduce edema while the latter will inhibit stone-induced ureteral spasm, thus maintaining peristaltic rhythm [30, 42, 43].

However, medical expulsive therapy (MET) should only be used in favorable conditions for spontaneous stone passage. Patients who elect for MET should have well-controlled pain, no clinical evidence of sepsis, and adequate renal functional reserve. Patients should be followed with periodic imaging studies to monitor stone position and to assess for hydronephrosis. Since patient complaints and stone size do not predict future renal function loss and time to permanent renal injury cannot be easily estimated, intervention should be recommended for any patient with persistent obstruction, failure of stone progression, or recurrent colic pain.

#### α-Adrenergic antagonists and calcium channel blockers

The presence of α- and β-adrenergic receptors has been demonstrated in human ureters. α1-Adrenergic receptors, particularly subtype α1d, are present in high density in the lower ureteral segment and may play an important role in lower ureteral physiology [44]. Norepinephrine is the main alpha-agonist and exerts a positive chronotropic and inotropic effect on the ureter. As a result, stimulation of α-adrenergic receptors decreases the volume of urine flow through the ureter.

α-Adrenergic antagonists are able to inhibit the basal tone and peristaltic frequency, dilating the ureteral lumen and facilitating in stone passage [45]. Several investigators have shown the utility of α1-blockers and their spasmolytic action in the active expulsion from the distal ureter [31, 46]. Tamsulosin may increase the urine bolus, and thus the pressure, above the stone; at the same time, the agent may decrease peristalsis, and thus the intraureteral pressure, below the stone. The net effect is an increased intraureteral pressure gradient around the stone, which ultimately results in a stronger expulsive force [35].

Yilmaz et al. evaluated tamsulosin, terazosin, and doxazosin alone compared with watchful waiting and found a significant increase in spontaneous stone passage with all three alpha-blockers (79, 78, 76, and 53%, respectively) [47]. A recent meta-analysis of 11 randomized clinical trials in more than 900 patients concluded that alpha-blockers increase the rate of spontaneous stone passage by 44% [48].

Moreover, α1-blockers reduce the need for analgesia by decreasing the frequency of peristaltic contractions in the obstructed ureteral tract, thus decreasing the frequency of ureteral colic [49]. There may be a double action of tamsulosin on the control of pain associated with ureteral colic; one on the smooth muscle, preventing spasm, and a second on C-fibers or sympathetic postganglionic neurons, which also block pain conduction to the CNS [50]. In addition, tamsulosin drastically decreases the need for hospitalization (10 vs. 27.5%), as well as the need for endoscopic procedures (0 vs. 13%) [31].

Calcium channel blockers such as nifedipine represent a valid and well-established pharmacologic treatment for urolithiasis owing to their spasmolytic action on the ureter.

The primary functional anatomic unit of the ureter is the smooth muscle cell, which functions in response to changes in calcium ion concentration. At the most fundamental level, an increase in calcium concentration results in relaxation. Ureteral stones induce ureteral spasm, which results in arrest of stone passage. Studies in both animal and human ureters show that calcium antagonists, namely nifedipine, inhibit the quick phasic contractions without affecting tonic activity [42].

Porpiglia et al. showed that medical treatment with nifedipine and deflazacort was both safe and effective, as evidenced by increased stone expulsion rate, decreased expulsion time, and reduced need for analgesic therapy [42]. Borghi et al. may have provided the most compelling evidence for the isolated effect of nifedipine when they compared nifedipine plus methylprednisolone with prednisolone alone in ureteral stones of up to 15 mm, and reported a success rate of 87% in the nifedipine arm compared with 65% in the control arm [51].

Two studies have compared alpha-blockade with calcium channel blockade with regard to spontaneous stone passage, with both finding an advantage for tamsulosin. Dellabella et al. evaluated patients with ureteral stones of greater than 4 mm and found tamsulosin to be the most effective, with a 97% success rate and an average of 72 hours to passage compared with 77% for nifedipine, with an average of 120 hours to passage [50]. Porpiglia et al. compared tamsulosin plus deflazacort with nifedipine plus deflazacort in a control group. Although not as significant as the findings in the study by Dellabella et al., there was a slight advantage of tamsulosin over nifedipine for overall effect (85 vs. 80%) and days to passage (7.7 vs. 9.3 days) [52].

Nifedipine blocks all ureteral contraction, while tamsulosin significantly reduces it, but still maintains some baseline activity. Thus, both agents work well to block the disorganized counteractive contractile activity associated with ureteral spasm, but the possibility of maintaining some degree of antegrade peristalsis allowed by alpha-blockade may explain the slight advantage [32]. Therefore, it is advocated to use tamsulosin as a first-line approach for the outpatient management of patients with distal ureteral stones.

Other studies that have been recently published, challenging the use of both alpha-adrenergic antagonist and calcium channel blockers. One of the studies by Robert Pickard established that neither an alpha-blocker, tamsulosin, nor the calcium channel blocker, nifedipine, showed any clinically useful benefit for expediting the spontaneous passage of stones and thereby decreasing the number of surgical interventions [53]. This multicenter trial was randomized with 1167 participants and they found by 4 weeks 80% of the patients taking placebo, 81% of the patients taking tamsulosin, and 80% of the nifedipine group did not need surgical intervention. However, there is enough evidence that clearly proves the beneficial effect on pain control of tamsulosin to make it useful in treatment of renal colic as part of a combination treatment strategy.

### Combination therapy

Based on data that suggest a higher rate of spontaneous stone passage, fewer days lost from work, and fewer surgical procedures, some urologists advocate a more aggressive medical approach. This treatment plan is intended for short-term use only but may benefit selected patients who can take medications reliably. A combination of drugs can be used together to improve the chances of spontaneous stone passage and alleviate renal colic discomfort.

A typically used combination therapy to facilitate spontaneous expulsion of urinary calculi consists of:

- ketorolac or similar NSAID for 5 days
- tamsulosin or nifedipine for 7 days
- levofloxacin or trimethoprim/sulfamethoxazole for 7 days
- an oral opioid pain medication as needed for breakthrough pain
- metoclopramide or prochlorperazine as needed for control of nausea.

Most ED physicians (76%) use ketorolac for pain management in renal colic, either alone (42.3%) or in combination with morphine (33.7%) [1]. A double-blind, randomized controlled trial demonstrated that the combination of intravenous ketorolac and morphine was superior at reducing pain scores and the need for rescue morphine compared with single-agent therapy [54].

Combination therapy may also increase the efficacy of expulsive therapy. Both ureteral spasm and edema play a role in preventing stone passage. In this regard, the combination of nifedipine (an antispasmodic) and a corticosteroid (antiedema agent) is recognized to be well-tolerated and effective in promoting ureteral stone passage [30].

Because it is widely recognized that infection within the ureter is a possible cause of calculus retention, it seems advisable to include an antibiotic in the standard approach to the patient with a symptomatic ureteral stone. One week of levofloxacin 250 mg could be an appropriate and reasonable measure in this setting [31].

**Straining the urine**

Stone analysis is extremely important in the evaluation of a patient with urolithiasis for stone preventive therapy. Knowing when a calculus is going to pass is impossible, regardless of its size or location. Therefore, straining of the urine of patients on MET should be continued until the stone is actually collected.

## 67

## Management of Stones in Horseshoe Kidneys

*Chandra Shekhar Biyani & Adrian D. Joyce*

*Department of Urology, St James' University Hospital, Leeds, UK*

### Introduction

Renal fusion anomalies can be broadly divided into two distinct types: horseshoe kidneys and cross-fused ectopia. Horseshoe kidneys are the commonest type of renal anomaly and have been reported to have an incidence of 1 in 400–700 live births in both autopsy and radiographic data [1, 2]. There is a male preponderance for this condition with a male-to-female ratio of 2:1. No genetic predisposition is known and horseshoe kidneys are frequently diagnosed incidentally and in isolation for adult patients, but may be part of a syndrome in the pediatric population, where it is estimated that 23% of patients with horseshoe kidney have other severe associated malformations, which may be gastro- intestinal, musculoskeletal, neurological, or most commonly urogenital anomalies [3]. There are several syndromes that are commonly linked to horseshoe kidneys including Down's syndrome, Turner's syndrome, and Trisomy 18.

### Development

Normal kidney development occurs at the fourth week of gestation from the fusion of the ureteric bud and metanephric blastema. The kidney is originally formed in the pelvic location and ascends with the growth of the body, in particular the sacral and lumbar regions during fourth to ninth weeks of gestation. Primitive renal vessels that originate from the pelvic aorta degenerate as the vascular supplies gradually arise from the proximal aorta. As the kidneys ascend through the arterial fork, they may be pushed together too closely and become fused at the lower poles. A more recent theory suggests that fusion may be the result of abnormal migration of the posterior nephrogenic cells which then fuse with the lower poles of the kidneys, forming an isthmus [4]. Notochord is necessary for correct positioning of the metanephric kidney and the axial sonic hedgehog (*ASH*) gene signal is essential step for kidney positioning along the mediolateral axis. Kidney fusion may occur with disruption of notochord or the *ASH* gene [5]. The ascent of the fused lower pole kidneys terminates just below the inferior mesenteric artery and oftens lie between the L1 and L4 vertebral levels (Figures 67.1 and 67.2).

Horseshoe kidneys are located anterior to the aorta and inferior vena cava. The fused lower poles of horseshoe kidneys are bridged by either functional renal tissue or fibrous tissue. As a consequence of the fusion at the lower poles, the renal pelvis fails to rotate medially and consequently remains ventrally located. This results in the ureter exiting the renal pelvis ventrally and more superiorly, and the longitudinal renal axis converges medially [6]. Matusmoto et al. [7] classified horseshoe kidneys into five types: Type A (a), fused at the upper poles; Type A (b), fused at the lower pole; Type B (a), fused by fibrous tissue; Type B (b), fused directly; and Type B (c), fused by mediators. Graves [8] proposed a classification system (Table 67.1) with six basic patterns of arterial supply for each horseshoe kidney segment.

A horseshoe kidney by itself is asymptomatic; however, due to the anatomy of high ureteric insertion, the presence of the isthmus, and the ventral orientation of the renal pelvis such kidneys are more prone to certain complications which include recurrent infections [9], renal stones, pelviureteric junction obstruction, vesicoureteric reflux [10], and renal tumor.

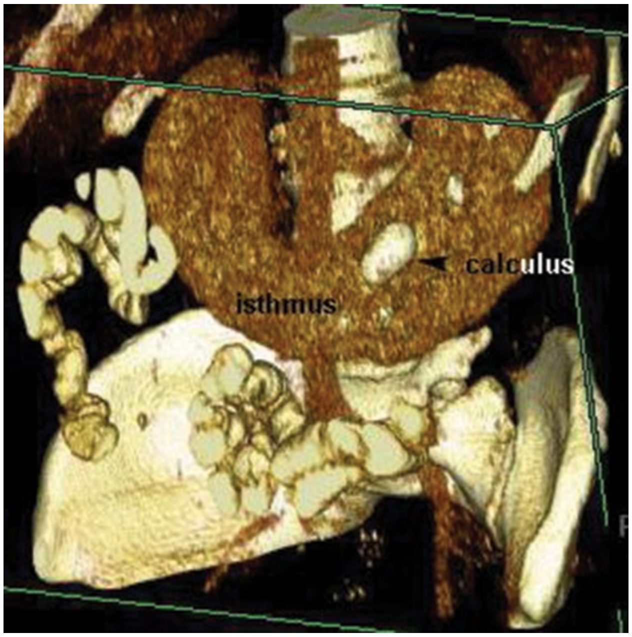

**Figure 67.2** Coronal oblique view with three-dimensional reconstruction showing the ventrally orientated lower pole and isthmus.

**Table 67.1** Arterial vascular pattern of horseshoe kidneys.

| | |
|---|---|
| Type 1 | The arterial supply may follow the normal pattern with a single renal artery supplying the upper, middle, and lower segments. |
| Type 2 | Upper and middle segments may be supplied by a single renal artery with a branch from the aorta entering each lower segment. |
| Type 3 | The arteries to the lower segment arise from the aorta by a common trunk and upper and middle segments are supplied by a single renal artery on either side. |
| Type 4 | All three segments are supplied by separate arteries arising from the aorta. |
| Type 5 | The isthmus may be supplied by arteries arising above or below the isthmus; these may be unilateral or bilateral and may originate from the aorta, independently, or by a common trunk. |
| Type 6 | The fused lower segments may be supplied by arterial branches from the common iliac artery or rarely from the internal iliac artery (hypogastric) or middle sacral artery. |

**Table 67.2** Endourological considerations in horseshoe kidney.

| Anatomic variations | Effect of variations | Therapeutic adjustments |
|---|---|---|
| Incomplete rotation | Medially directed calyces | May require more medial percutaneous puncture |
| Abnormally oriented calyces | Acute angle at infundibulum | Difficult or incomplete access to collecting system |
| Lack of ascent | Low-lying kidney | Lower puncture may be necessary |
| Lack of usual pararenal support | Mobile kidney | Percutaneous puncture more demanding |
| Renal pelvis anterior | Increase distance from skin | Long instruments necessary |
| Arteriovenous variations | Single renal artery in 30% | Vascular hazards |

## Urolithiasis

Urolithiasis is the commonest complication related to horseshoe kidney and is estimated to be 21–60% [11]. This is likely to be a consequence of impaired urinary drainage leading to stasis and infection predisposing to calculi formation. The treatment of urolithiasis poses a unique challenge due to the variable vascular and renal anatomy and the predisposition to multiple and large staghorn-like calculi [3]. The abnormal orientation of the renal pelvicalyceal system further increases the potential complexity for stone management (Table 67.2).

Minimally invasive intervention for the treatment of urolithiasis in a horseshoe kidney is now widely accepted with good stone-free results and low complication rates [12, 13]. However, the clinical decision making process must balance the likelihood of stone-free rates against the intervention risk and potential for complications.

## Extracorporeal shock-wave lithotripsy

Extracorporeal shock-wave lithotripsy (ESWL) has revolutionalized the treatment of renal stone disease. ESWL has been advocated as the primary treatment modality for stones less than 20 mm [11]. Sheir et al. retrospectively reviewed 198 patients with anomalous kidneys and showed that ESWL is a safe and reliable method of treatment with a stone-free rate of 72% [14]. This is comparable with the stone-free rate of a solitary stone, in a normal kidney, at an average of 72.8%; however, the reported range for stone-free rates in horseshoe kidneys is 33–79% [14, 15].

The anatomy and orientation of a horseshoe kidney presents a challenge to the use of ESWL as the renal pelvis is ventromedially orientated and approximately a third may have a concomitant ureteropelvic junction obstruction. Locating these calculi can be difficult as the vertebrae may act as an obstacle and in some patients there may be associated vertebral anomalies. The skin-to-stone distance may also be increased, resulting in difficulty in positioning focal point (Figure 67.2). Prone position and "blast path" may need to be used to target these awkwardly positioned calculi [16]. A better stone-free result can also be achieved when a second-generation lithotripter is used [14]. Concerns have also been raised, due to the high ureteric insertion of the ureter, as to whether fragments post-ESWL are able to pass spontaneously. The most important predictor for failure of ESWL or significant residual calculi needing retreatment is location, stone density, size, and number. Various studies have reported a stone-free rate of 39–66% (Table 67.3). Ancillary procedures may need to be used pre-ESWL such as percutaneous nephrostomy, double-J ureteric stents, or ureteral catheterization and these should be decided on a case-by-case basis. It is important to emphasize that there have been no prospective studies comparing the different treatment modalities in this group of patients but ESWL may be beneficial in patients with small calculi.

Complications post-ESWL in horseshoe kidneys are similar to those performed in normal kidneys. Renal colic, mild haematuria, and urinary tract infection are considered mild and may be treated conservatively and medically. Steinstrasse is rare but a known complication post-ESWL which can result in ureteric obstruction requiring endoscopic retrieval of these calculi. The risk factors for steinstrasse post-ESWL in a normal kidney are stones greater than 2 cm in a dilated system, proximal located calculi, and the use of high kV for disintegration [20].

## Percutaneous nephrolithotomy

Percutaneous nephrolithotomy (PCNL) is a well-established technique in the treatment of urolithiasis in normal kidneys and often widely used as first-line treatment in horseshoe kidneys, especially when calculi are larger than 2 cm or after failed ESWL.

As described, the horseshoe kidney lies lower than a normal kidney. The renal pelvis is ventrally orientated and in most cases the lower poles are connected by an isthmus which may be fibrous or viable renal tissue. The long axis of the kidney is orientated in the sagittal plane, such that the posterior calyces are orientated dorsomedially and the frontal row points dorsolaterally. Thirty percent of horseshoe kidneys have a single renal artery on either side [21] but the blood supply is variable with accessory vessels arising from any part of the abdominal aorta, bifurcation, or iliac arteries and inserting into the renal hilum (see Table 67.1). There are no accessory vessels in the dorsal aspect of the horseshoe kidney [22].

Taking all the above anatomical factors into consideration, percutaneous access of horseshoe kidney is relatively safe and often best approached via the most superior calyx (see Chapter 18 and Video 18.1 on upper pole PCNL). Inadvertent damage to the pleura is uncommon with an upper pole puncture in a low-lying horseshoe kidney. The posterior calyx is relatively easily

**Table 67.3** Main outcomes of extracorporeal shock-wave lithotripsy.

| Study | Study period | No. of patients | Mean stone burden (cm$^2$) | Stone free (%) | Significant fragment (%) | Auxiliary treatment rate (%) |
|---|---|---|---|---|---|---|
| Tunc et al. [17] | 1990–2002 | 45 | 2.24 ± 0.6 | 66.7 | 22.2 | – |
| Ray et al. [18] | 1994–2010 | 41 | 0.91 ± 0.716 | 39.1 | – | 72.7 |
| Torrecilla Ortíz et al. [19] | 1988–1999 | 32 | – | 54 | 30 | – |

accessible with a direct puncture in a dorsoventral direction and the puncture site more medially located in comparison to normally orientated kidney. Apart from several accessory vessels to the isthmus, there are no major blood vessels arising from the dorsal aspect of the kidney. The risk of access-related major vascular hemorrhage is no higher than in normal kidneys.

Access for PCNL can be performed under ultrasound, fluoroscopic, or computed tomography (CT) guidance. The basic principle of achieving an atraumatic puncture of the renal calyx should be adhered to if possible, regardless of the modality used. The safest point of puncture is the middle of the calyx following Brödel's line. However, the superior calyx is usually the chosen puncture site for a staghorn calculus or stones within multiple calyces. This is because the anatomic access with a posterior puncture allows increased maneuverability of the nephroscope within the collecting system and the option to use flexible instrumentation to access stones in peripheral calyces.

Ultrasound can be used to guide puncture into the superior calyx if the collecting system is hydronephrotic or predilated with fluid/contrast retrogradely. However, the lower pole is also often poorly delineated and as a consequence the view of the calyx may be suboptimal for guiding access puncture [23].

Fluoroscopically guided puncture is the standard technique used in our institution. After placing a ureteric catheter. The patient is then turned to the prone position with the C-arm placed vertically. The pelvicalyceal system is distended with contrast media and the C-arm can be rotated +30 to −30° to evaluate the calyceal anatomy. An 18G sheath needle is used to puncture the skin and advanced into the desired calyx under fluoroscopic guidance (Figure 67.3). The needle is advanced in increments and aims at the calyceal cup. When the needle is moving with respiration, the C-arm is then rotated obliquely to an angle such that the length of needle is visualized and the needle is advanced under fluoroscopic guidance. The needle should be advanced ideally to puncture the epicenter of the calyx and the needle tract should be in the orientation of the infundibulum. As the tract may be longer for a horseshoe kidney, longer instruments may be necessary. The lower pole and pelvis are more anteriorly facing than is usual; lower pole lateral entry may damage the large anterior division arteries or accessory branches from the iliac artery [24]. Therefore, lower pole calyx puncture is avoided in our practice unless there is no other alternative. Once the puncture site is secured, an Amplatz super-stiff guide wire (0.035 in, 180 cm; Boston Scientific) is advanced, preferably down the ureter (Figure 67.4), and the tract is dilated using a NephroMax™ High Pressure Balloon (Boston Scientific) catheter and a 30 Fr PTFE sheath. The inflated balloon catheter is advanced over the Amplatz super-stiff guidewire until the distal tip of the balloon is positioned in the calyx. The other option is to dilate the tract serially with telescopic metal dilators (Keymed; Olympus) to accommodate a 26 Fr (up to 30 Fr) Amplatz sheath (Cook Urology) (Figure 67.5).

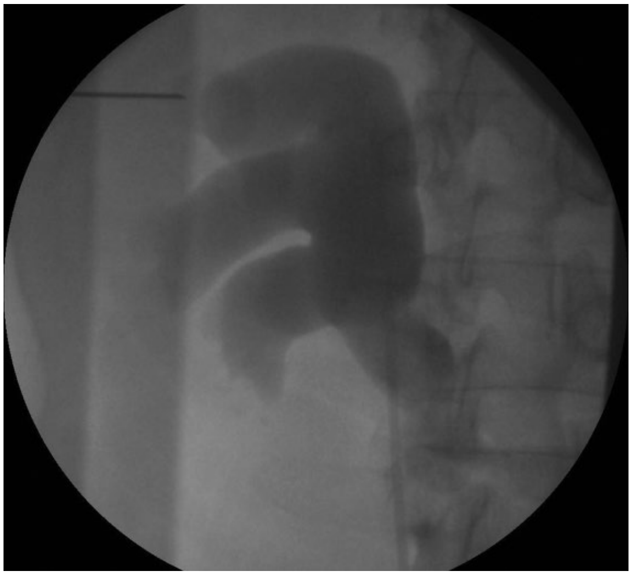

**Figure 67.3** The 18G-sheathed needle is aiming at the calyceal cup.

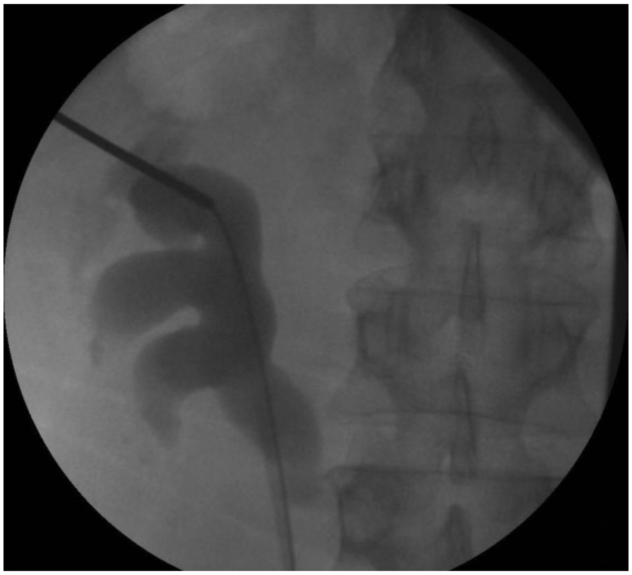

**Figure 67.4** The telescopic metal dilator is inserted within the upper pole calyx with Amplatz superstiff guidewire in the ureter to anchor the tract.

A rigid nephroscope is used to remove the calculi using either an ultrasonic or lithoclast lithotripter to disintegrate the stones. Having a flexible cystoscope or nephroscope may allow access to abnormally located calyces. Stones can be removed sequentially through the tract with various

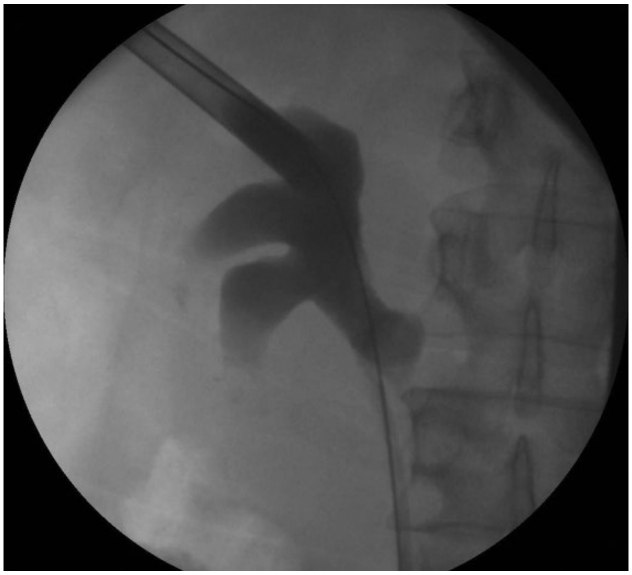

**Figure 67.5** A 26 Fr amplatz sheath is inserted into the upper pole calyx.

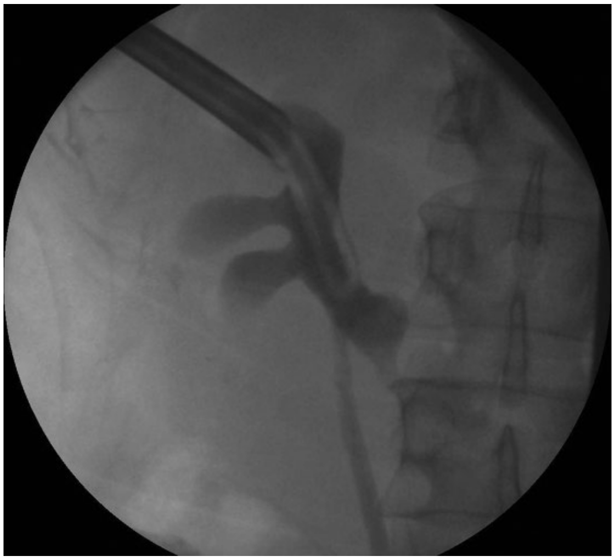

**Figure 67.6** A Foley catheter is sited as a covering nephrostomy at the end of the procedure.

stone-grasping devices. At the end of the procedure, we usually site a Foley catheter (20 Fr) as a covering nephrostomy to tamponade the tract for at least 24 hours (Figure 67.6). This will then be clamped and if the patient is asymptomatic the nephrostomy will then be removed on the ward. A post-procedural nephrostogram will only be performed if there is concern with regard to injury or potential distal ureteric stones causing obstruction.

CT-guided access is reserved for complex situations resulting in challenging access due to the patient's associated vertebral anomaly (e.g. severe kyphoscoliosis), extreme obesity, or hepatosplenomegaly. CT is normally acquired in a *prone* position and can also be used for surgical planning prior to PCNL. Retrorenal or posterolateral displacement of the bowel can be associated with horseshoe kidney and the bowel may occasionally act as an obstacle to percutaneous access. In these situations, an initial unenhanced CT abdomen and pelvis with 2 mm reconstruction (CT kidney–ureter–bladder) may be performed as an overview. Subsequent images for CT-guided procedure can be acquired by obtaining a volume of area of interest and reconstructed with 3 mm slice thickness. It is paramount in this case that the patient will be able to tolerate a prolonged prone positioning. Once access is obtained, a nephrostomy tube can be left *in situ* for subsequent access and the tract can be dilated as described above under general anesthetic.

The stone-free rate post-PCNL in the treatment of renal calculi in horseshoe kidney is similar to that in a normal kidney at 80%. The complication rates reported are also comparable with that of normal renal PCNL with minor complications such as hematuria and infection reported at 15%. Major complications, for example hydropneumothorax requiring insertion of a chest drain, have an incidence of 2% [24] (Table 67.4).

## Ureteroscopy

Retrograde digital flexible ureteroscopy is becoming a more frequently used modality, especially for stones less than 15 mm in diameter, using holmium:YAG laser for stone disintegration. However, reported case numbers are small and retrospective and there may be issues relating to ureteric access requiring prestenting. These cases will generally require use of an access sheath and postoperative stent insertion. In addition, access to the lower pole may be difficult in some patients and relocation of the stone from the lower pole to the upper pole may be necessary. To date such cases have generally been managed in specialist stone centers that can offer the full range of stone management [31]. A recent systematic review identified three studies. A success rate of 78% was noted in 41 patients. A ureteral access sheath was used in all patients [32].

## Laparoscopic pyelolithotomy

While most stones can be efficiently managed using endourologic techniques, the use of laparoscopy for the management of urolithiasis has a limited role. Laparoscopy has been used alone or in combination with other endoscopic procedures. Delineation of vascular anatomy by preoperative CT angiography/urography is recommended before surgery as it helps in surgical

**Table 67.4** Percutaneous nephrolithotomy outcomes from different studies.

| Study | Study period | No. of patients | Superior pole access (%) | Stone free (%) | Secondary procedures (%) | Complications, major/minor (%) |
|---|---|---|---|---|---|---|
| Ozden et al. [25] | 1997–2008 | 46 | 68 | 80 | 8 | 2/14 |

planning. A transperitoneal approach is commonly used and pyelolithotomy is easier as the pelvis is anteriorly rotated and can be identified easily [33–35].

## Summary

Urolithiasis with horseshoe kidney is of diverse etiology, requiring a carefully planned, individualized diagnostic and management approach. ESWL is the preferred treatment for the majority of patients with urolithiasis. However, ESWL monotherapy for stones in horseshoe kidneys is likely to provide good fragmentation but stone clearance is suboptimal due to anatomical factors. Excellent stone-free rates can be achieved with ureteroscopy and PCNL in properly selected cases, with the best approach being via the upper pole

See Chapter 18 and Video 18.1 regarding upper pole access.

## Introduction

Renal ectopia signifies an abnormal location of a kidney outside of the orthotopic renal fossa. This is due to abnormal ascent or rotation of the kidney during embryological development. These kidneys may be located in the pelvis, mid-abdomen, or even the thorax. The most common type of renal ectopia is the pelvic kidney, which has an estimated occurrence of 1 in 2100–3000 [1]. Although most patients with pelvic kidneys are asymptomatic, some may have pain due to stones or hydronephrosis [2]. The anatomic location of a pelvic kidney may make treatment of such pathologies difficult, requiring strategic preoperative planning in determining the optimal therapeutic approach. This chapter provides an overview of the development of pelvic kidney, and treatments of associated pathologies excluding neoplastic conditions. In addition, we will discuss the management of patients with stones in transplant grafts, an "acquired pelvic kidney."

## Embryology

During the fourth or fifth week of gestation the ureteric bud interacts with the metanephrogenic blastema. This induces proliferation and differentiation of the blastema into glomeruli and tubules. During the sixth to ninth weeks of gestation the kidneys normally migrate cranially from the pelvis to the ipsilateral renal fossa at the T12–L3 vertebral level. During the ascent, the kidneys undergo a 90° axial rotation from an anterior to ventromedial direction.

Incomplete migration of a kidney leads to an ectopic location. Various factors account for this aberrant process including incomplete development of the ureteric bud or metanephrogenic blastema, genetic defects, teratogens, and vascular abnormalities [3–6]. Renal ectopia also has an increased association with genital defects with an incidence of up to 15% [7]. In females, ectopic kidneys may be associated with bicornuate uterus and hypoplasia or agenesis of the uterus/vagina; in males, the most common genital anomalies associated are hypospadias and cryptorchidism [6, 8, 9]. While most patients with renal ectopia have a normal contralateral kidney, there is an increased incidence of contralateral renal agenesis of up to 10% [6, 10, 11].

Complete failure of ascension results in a pelvic kidney. In this case, a kidney remains in its initial location anterior to the sacrum in the retroperitoneum (Figure 68.1). Due to incomplete rotation, the renal hilum may face anteriorly. The ureter may have a high insertion into the pelvis but usually maintains its orthotopic insertion into the bladder. Arterial vascular supply may be variable, including from the distal aorta, common iliac, or external iliac arteries [4, 6, 12, 13] (Figure 68.2).

## Nephrolithiasis

The evidence that stones are more prevalent in pelvic kidneys is discordant. While a 1971 study by Dretler et al. did not find an increased prevalence, a later study in 1994 by Gleason et al. demonstrated this association [2, 14]. Gleason noted that hydronephrosis was present in 56% of pelvic kidneys. Impaired urinary drainage in such kidneys has been proposed to play a role in stone formation. However, underlying metabolic factors are likely the main driver [15].

## Shock-wave lithotripsy

Variable success has been reported with using shock-wave lithotripsy (SWL) to treat patients harboring stones in pelvic kidneys. Stone-free rates ranging from 25 to 82% at 3 months after an initial SWL session have been reported [16–19]. The main limitation is the location of the kidney within the bony pelvis and its adjacency to bowel, which may make shock-wave targeting difficult. Various techniques have been used to improve targeting during SWL in such cases. Jenkins et al. used ureteral catheters to mark general stone position for fluoroscopic guidance during SWL [20]. Contrast can also be injected into the collecting system through stents to facilitate targeting.

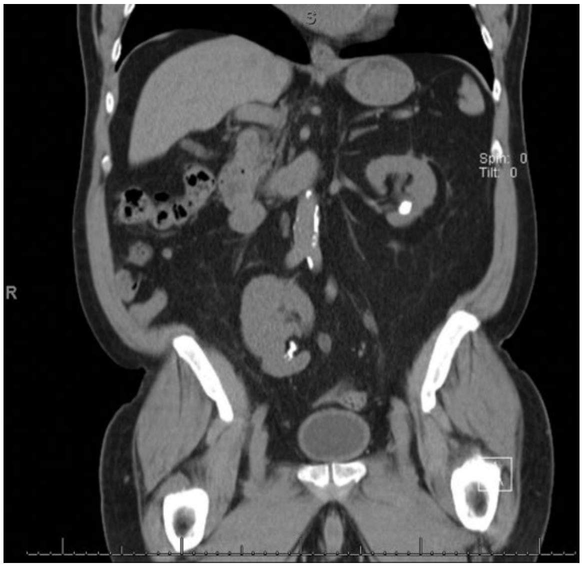

Figure 68.1 Calculus within the right pelvic kidney.

Presence of hydronephrosis may also limit success in these cases [12]. Demirkesen et al. reported significantly lower stone-free rates with SWL in pelvic kidneys (38%) compared to orthotopically located kidneys (78%) [18]. However, Talic et al. have reported a much higher success with SWL in those with stones in pelvic kidneys, 82% [17]. The varying results may be due to patient selection, technique, and the lithotripter utilized.

Proper positioning has been shown to be critical to SWL success in pelvic kidneys [17]. The use of prone positioning for stones located below the iliac crest is recommended to facilitate targeting and limit bony structures from impeding shock waves [20, 21]. If calculi are visible superior to the pelvic brim, a supine position can be used [17].

## Ureteroscopy

Ureteroscopy has become a reliable approach as both a salvage and first-line option to treat patients with stones in pelvic kidneys. This has been enabled by advances in instrumentation including the holmium laser, ureteral access sheaths (UAS), nitinol baskets, and deflectable, flexible ureteroscopes [22, 23]. These advancements have helped overcome the anatomic challenges of the pelvic kidney including ureteral tortuosity and acute angles of access to the ureteropelvic junction (UPJ) and lower pole calyces (Figure 68.3). The use of a ureteral access sheath in particular can help to straighten a tortuous ureter and facilitates access to the renal pelvis [24].

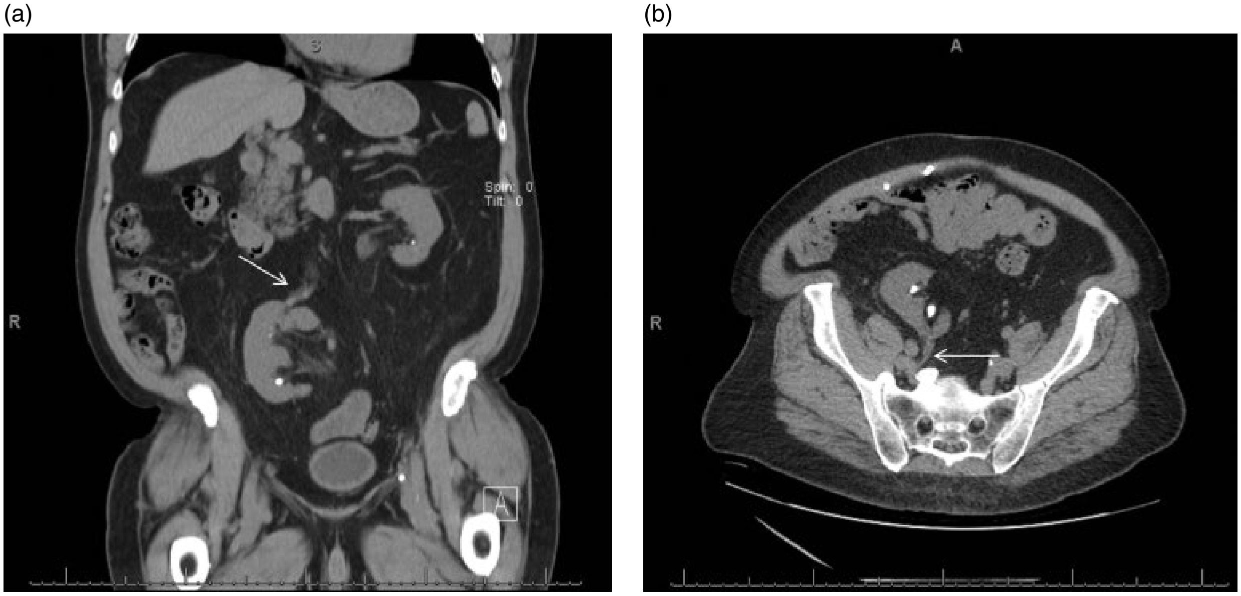

Figure 68.2 Abnormal vasculature of pelvic kidney from (a) coronal and (b) axial views.

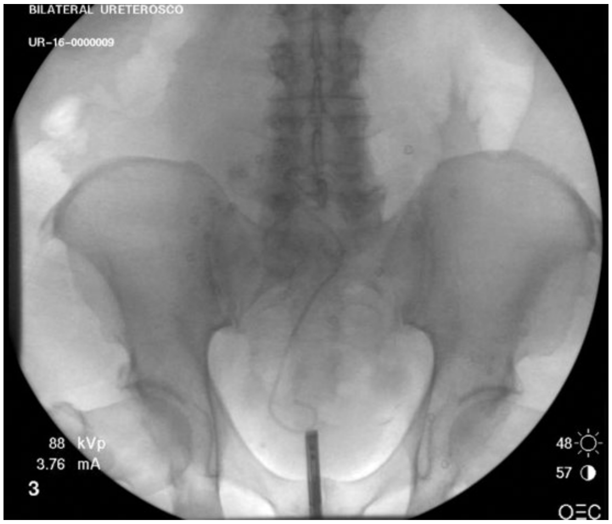

**Figure 68.3** Stent placement demonstrating ureteral tortuosity of pelvic kidney.

Despite the increasing use of ureteroscopy, studies involving its use in anomalous kidneys are scarce. Weizer et al. reported a 75% stone-free rate at 1–3 month follow-up for four pelvic kidney patients who had flexible ureteroscopy performed. In this study, a UAS was used in 50% of the patients [24]. A study by Alkan et al. reported a 100% stone-free rate in three pelvic kidney patients; a UAS was only used in one patient due to failed placement in the other two subjects [25]. Singh et al. achieved 88% stone-free rate in 22 patients with anomalous kidneys for which a UAS was used in all cases [26]. There are two studies, however, which did not utilize a UAS in ureteroscopy and still achieved 75 and 84.6% treatment success rates in populations of four and 26 patients respectively as defined by <2 mm stone burden after ureteroscopy on follow-up [27, 28].

In these studies, position of the stone was a key factor in achieving successful stone-free rates. Singh et al. noted decreased stone-free rates in patients with lower pole stones (60.4%) compared to those with upper, middle, or renal pelvis stones (94.4%) [26]. As with ureteroscopy in orthotopically located kidneys, stone burden may also limit successful treatment in pelvic kidneys. A total stone burden size of >2 cm is associated with higher failure rates [26, 29].

## Laparoscopy-assisted percutaneous nephrolithotomy

Percutaneous nephrolithotomy (PCNL) is an effective approach for treating patients with large stones in pelvic kidneys. With the presence of bowel and other visceral structures adjacent to the pelvic kidney, access often necessitates a different approach for which direct visualization and manipulation with laparoscopy is used to limit injury to these structures.

PCNL in a pelvic kidney was first described by Eshghi et al. in 1985 for treatment of a patient with a staghorn stone [30]. Subsequent reports with this approach noted 100% stone-free rates in 15 and two patients respectively [31, 32]. In the aforementioned cases, a retrograde external ureteral stent was initially placed to guide fluoroscopic access. Patients were placed in a supine Trendelenburg position to assist in bowel displacement. Pneumoperitoneum was established and two ports were placed: 10 mm port through the umbilicus for the camera and a 5 mm assistant port in the lower quadrant contralateral to the pelvic kidney. Others have utilized an additional 10 mm port in the ipsilateral lower quadrant [33]. Under direct visualization, a grasper was used through the 5 mm port to displace the bowel to visualize the pelvic kidney. An antegrade puncture was then performed using an 18G needle under both laparoscopic and fluoroscopic guidance. Subsequent steps mirrored those of a normal PCNL with wire access obtained followed by dilation and sheath placement (Figure 68.4). Methods for urinary diversion at the end of the procedure varied but generally included a double-J stent or a transperitoneal nephrostomy tube [31–33]. If an internalized ureteral stent is place for drainage at the end of the case, some have advocated closure of the nephrotomy with absorbable suture [33].

Various other approaches to PCNL for pelvic kidneys have been described in the literature. Troxel et al. reported an extraperitoneal approach for one patient in which a balloon was used to expand the extraperitoneal pelvic space and push the peritoneal contents cephalad to expose the pelvic kidney. This approach may theoretically reduce the risk of bowel injury [34]. In another case report, Monga et al. performed a posterior approach to a pelvic kidney in a patient by developing a tract just medial to the paraspinal muscles along the quadratus lumborum and psoas major. Stone-free status was achieved; however, the patient developed femoral neuropathy, which was still present 6 months postoperatively. The injury was likely related to trauma involving the dorsal divisions of the lumbar plexus along the psoas muscle incurred during dilation [35]. Thus, we do not endorse this approach. Goel et al. reported a transmesenteric approach to access a pelvic kidney. In this procedure, upon gaining laparoscopic visualization, a tract was established through the mesentery, taking care to avoid the mesenteric vessels. The advantage of this approach is that it limits bowel mobilization. A transmesenteric technique should only be used when the mesenteric vessels can be clearly indentified [36]. Other approaches that have been reported including trans-iliac and trans-sciatic [33, 37]. The latter should only be

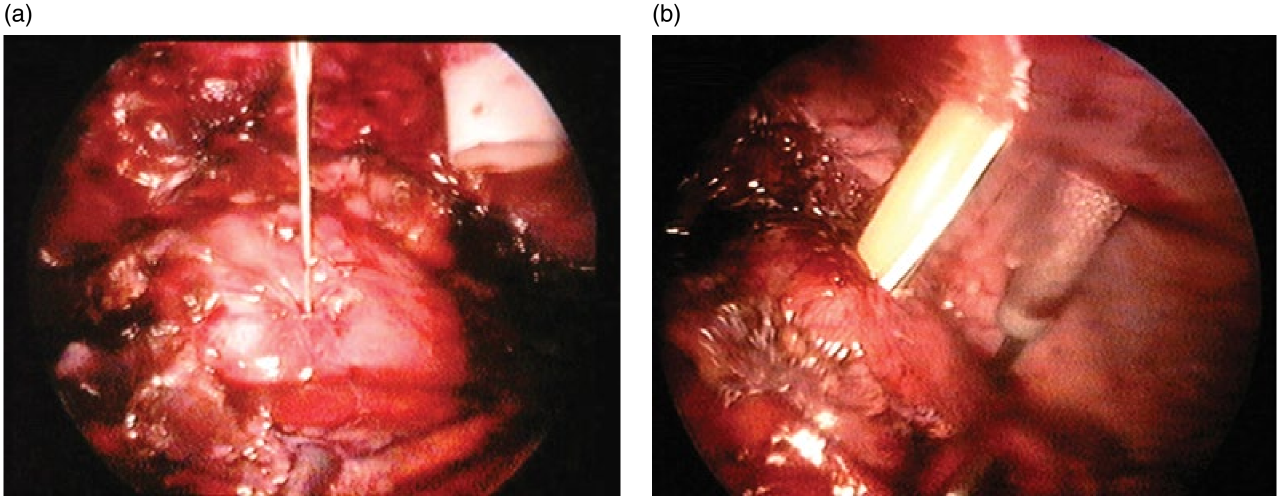

**Figure 68.4** (a) Antegrade puncture and (b) percutaneous access obtained under direct laparoscopic vision for percutaneous nephrolithotomy.

undertaken in cases where there is limited risk of injuring adjacent structures.

Laparoscopy-assisted mini-PCNL, in which a smaller tract and sheath are used, has been performed successfully in pelvic kidney patients. D'souza et al. reported an 88.9% stone-free rate in nine patients who underwent laparoscopy-assisted mini-PCNL. For this approach, after mobilization of the bowel, a 15 Fr tract to the pelvic kidney was established; a rigid mini-nephroscope was subsequently used for laser lithotripsy. Use of a smaller tract could reduce the chances of vascular injury and limit the risk of urine leak [38].

While laparoscopy has been used in a majority of PCNL pelvic kidney series, Desai and Jasani used ultrasound guidance in place of direct laparoscopic visualization. With the patient in a supine oblique position, an ultrasound probe was used to locate the pelvic kidney; pressure was then applied with the probe to displace bowel away from the planned puncture site. Access through an anterior approach in the area of the iliac fossa was then obtained. They were ultimately able to achieve stone-free status in five pelvic kidney patients without any bowel injuries reported. This method would avoid the complexities involved in laparoscopic access. However, this also requires the pelvic kidney to be mobile and displaced toward the abdominal wall for access. The use of ultrasound may also increase the risk of injury to bowel, especially in the setting of collapsed bowel that may not be visible on ultrasound [39]. Thus, this approach should only be considered in highly select cases.

Overall, PCNL for pelvic kidneys with large stone burden (>1.5 cm) has been shown to have a consistently higher success rate (88.9–100%) compared to SWL and flexible ureteroscopy in achieving stone-free status [31, 33, 38, 39]. However, this approach does carry the risk of more serious complications including bowel and nerve injury, bleeding, and intraperitoneal urine leak.

## Laparoscopic pyelolithotomy

Laparoscopy- or robot-assisted pyelolithotomy is a consideration in patients with large volume renal pelvic stones in such kidneys. This should not be undertaken in those with an intrarenal pelvis. These approaches allow for the removal of stones in one piece rather than in fragments. In addition, a flexible nephroscope may be used to facilitate stone evacuation, especially those located in calyces.

Urine leak was a problem encountered in early reported cases of laparoscopy in patients with pelvic kidneys. This was demonstrated in two separate case reports by Harmon et al., and Chang and Dretler published in 1996 [40, 41]. Both cases began with the patient in Trendelenburg position. After pneumoperitoneum, four trocars were placed in the lower abdomen (one in each lower quadrant, one infraumbilical, one midline). After bowel mobilization, the pelvic kidney was located and the pelvis was dissected free. A 2 cm pyelotomy was made after which stone was extracted with laparoscopic forceps. Due to the depth and location of the incision, Harmon et al. were not able to close the pyelotomy; subsequently a double-J stent, perirenal drain, and bladder catheter were left in place. The pyelotomy closed after a long period of bladder catheter drainage. In their report, Chang and Dretler closed their pyelotomy with polydioxanone suture and left a bladder catheter and double-J stent in place. The catheter was removed on postoperative day 1. A subsequent voiding cystourethrogram showed a leak at the pyelotomy site theorized to have been caused by ureteral reflux. The leak closed spontaneously with Foley catheter drainage [40, 41]. Placement of an externalized stent at the beginning of such cases allows one to assess the integrity of the pyelotomy closure as retrograde fluid can be injected to identify leaking sites [42].

The largest series of laparoscopy in patients with pelvic kidneys was reported by Elbahnasy et al. in which 10 of 11 patients were rendered stone-free (90.9%). They used a transmesenteric approach in those with left-sided stones [43].

Bozkurt et al. reported using a retroperitoneoscopic approach for such cases [44]. They inserted three ports in a triangular configuration in the lower pelvic region after pneumoretroperitoneum was established. A potential advantage of this approach is that if a urine leak occurs it would be contained to the retroperitoneum. In addition, this could reduce the risk of bowel-related complications.

The utilization of a robot-assisted approach facilitates closure of the renal pelvis and this is especially true if concomitant pyeloplasty is required. Nayyar et al. reported a robot-assisted laparoscopy that was performed in conjunction with a pyeloplasty. They utilized a transperitoneal approach in which a 1.3 cm renal pelvic stone was removed from a pelvic kidney with a UPJ obstruction. The authors noted that the use of a robotic interface allowed for easier dissection, stone extraction, and pyeloplasty compared to standard laparoscopy [45].

### Nephrolithotomy

A laparoscopic or robotic assisted approach may also be utilized to perform nephrolithtotomy. This may be a consideration in patients harboring stones in large calyceal diverticular cavities. The location of the stone may be identified with fluoroscopy or intraoperative ultrasonography. A nephrotomy is made based on the aforementioned targeting with imaging, the stone(s) removed, and the diverticular cavity fulgurated. Perinephric fat can be inserted into the diverticular cavity. Laparoscopy- and robot-assisted “anatrophic” nephrolithotomy has been reported in patients with large branched/staghorn stones in normally positioned kidneys [46, 47]. A preoperative computed tomography (CT) arteriogram should be considered if this is undertaken in patients with a pelvic kidney to identify the often-variable renal vascular anatomy.

### Open stone surgery

The need for open surgical stone removal in todays practice is rare and this would also hold true for patients with stones in pelvic kidneys [48, 49]. The development and utilization of the previously profiled techniques has dramatically reduced the need for open stone surgery including this patient cohort.

## Ureteropelvic junction obstruction

UPJ obstruction occurs more commonly in ectopic kidneys and is reported to be present in 22–37% of such renal units [2]. Renal malrotation, aberrant vasculature, and a high ureteral insertion may be contributory.

### Endopyelotomy

Endopyelotomy has been used to treat patients with UPJ obstruction since the early 1980s [50]. Although there are a number of reports profiling the effectiveness of endopyelotomy, the results with this approach are not as good or durable as those achieved with pyeloplasty and thus it should be considered mainly for pyeloplasty failure or for those not deemed to be good candidates for the aforementioned procedure [51–53].

The literature regarding endopyelotomy for congenital pelvic kidney, however, is sparse. The data are made up primarily of individual case reports and a few small series that group various forms of anomalous kidneys together (i.e. horseshoe, lumbar, pelvic, cross-fused ectopic). The largest report to date of antegrade endopyelotomy in ectopic kidneys involved nine patients, two of whom had a pelvic kidney. In both patients, a ureteroscopically placed Hunter–Hawkins catheter was used along with laparoscopic assistance to gain percutaneous antegrade access. Both patients demonstrated long-term success on follow up [54]. If antegrade access is already present in the form of a nephrostomy tube, then this can be safely used for subsequent antegrade access without the need for repeat laparoscopic assistance [55]. Laparoscopy-assisted PCNL can be combined with endopyelotomy if stones are present. This technique is not often utilized as laparoscopic repair has better long-term results [56].

While there are a number of reports regarding success with retrograde ureteroscopic endopyelotomy in normally positioned kidneys, we found only one publication in the literature regarding its utilization in a pelvic kidney [57–59]. In this single case report, the patient’s obesity and history of recurrent pyelonephritis discouraged traditional open or laparoscopic repair. A preoperative angiogram is recommended, CT angiogram or magnetic resonance angiogram, if this procedure is contemplated due to variable renal vascular anatomy. This will help guide the direction of incision. Intraluminal ultrasonography can also be used to define vascular relationships with the UPJ [60].

### Open pyeloplasty

Laparoscopy- or robot-assisted pyeloplasty is the preferred treatment approach for patients with UPJ obstruction in a pelvic kidney as recovery is enhanced due to limited invasiveness. However, there are patients for whom this may not be possible due to extensive adhesions or abnormalities of body habitus and thus an open surgical approach would be preferable. A large retrospective review of open pyeloplasty for congenital UPJ obstruction in ectopic pelvic kidneys included 43 patients between 1995 and 2010 at a single institution. All patients underwent open dismembered Anderson–Hynes pyeloplasty. There were no perioperative complications and an overall success rate of 82.6% was reported [61]. In select patients with a severe peripelvic fibrosis and an intrarenal pelvis, ureterocalicostomy should be considered [62, 63].

### Laparoscopic/robotic pyeloplasty

To date there are multiple reports and a small case series demonstrating good results with laparoscopic/robotic pyeloplasty in pelvic kidneys with UPJ obstruction [64–66]. Operative times were similar to patients with orthotopically positioned kidneys. If there is concomitant stone disease in the affected kidney, pyelolithotomy can also be performed [67, 68].

### Pyelovesicostomy

Pyelovesicostomy was first described in 1929 as management for UPJ obstruction in a patient with a pelvic kidney with crossed fusion [69]. Since then, there have been reports of its use in pelvic kidneys and transplant kidneys as well with excellent long-term results [70, 71]. In 2005, Davis and Wolf described their experience with laparoscopic pyelovesicostomy for UPJ obstruction in a patient with a pelvic kidney. The procedure had a short operative time with minimal blood loss and the patient had a durable response at follow up. Downsides to this approach include increased risk of pyelonephritis and bladder pain [72]. Others have subsequently reported success with a laparoscopic approach for this procedure [73]. The utilization of a robot-assisted platform would undoubtedly facilitate the reconstructive portions of this procedure.

## Transplant kidney

### Stone disease

Review of the literature shows that the incidence of stone disease in a transplanted kidney ranges between 0.1 and 6.7% [74]. Renal and ureteral stones in transplanted kidneys can be effectively managed with endourologic techniques. Options for management include the same techniques used in native kidneys: ureteroscopy, SWL, PCNL, and open stone and laparoscopic/robotic surgery with most patients being treated with the first three modalities. When performing ureteroscopy, identifying and accessing the ureter in a retrograde fashion can be difficult and the lateral course of the ureter can make navigation into the kidney difficult. A recent retrospective study investigated outcomes of renal transplant patients treated with ureteroscopy for stone disease and showed that there were no major complications; most patients were able to go home on the same day and 71% were rendered stone-free [75]. Intubation of the transplant ureteral orifice may be challenging and require the use of a curved-tip angiographic catheter and a flexible cystoscope. The safety of utilizing an access sheath has not been determined due to the low numbers of reported cases for this cohort. Stones under 1.5 cm can also be treated with SWL, although its use is limited by the position of the allograft within the bony pelvis that can make stone localization difficult and attenuate shock-wave energy. Furthermore, the course of the transplant ureter may limit passage of stone fragments passage. PCNL is the preferred approach for removing large stones from transplants grafts and excellent results are achievable [76–78]. The utilization of ultrasound- or CT-guided access is frequently required to limit the risk of injuring adjacent structures especially bowel. While McAlpine et al. described their successful experience with outpatient tubeless PCNL in a transplant patient, we do not endorse such an approach in this higher-risk cohort [79].

### Ureteral stricture in transplant grafts

Along with stone disease, urologic complications after renal transplant include urine leak and ureteral stricture. Urine leak from the ureteral reimplantation can be managed with observation if a drain is in place but placement of a nephrostomy tube may be required for management. Some of these patients will develop a ureteral stricture. The incidence of ureteral stricture requiring intervention is reported in a recent large review to be 2.5% [80]. The placement of a ureteral stent at the time of transplantation to limit ureteral complications is undertaken at many transplant centers [81, 82]. While some patients who develop short strictures can be managed with balloon dilation, the results are inconsistent and many require formal reconstruction [83]. The length of available ureter and location of abnormality normally dictates the surgical approach; in a transplant setting, the short ureter limits treatment options.

This may include the utilization of the patient's ipsilateral native ureter for ureteroureterostomy, resection of the strictured segment and reimplantation if there is adequate remaining ureter, pyelovesicostomy, Boari flap, and appendiceal and bowel interposition [70, 71, 80, 84, 85]. Patients who are not thought to be good candidates for reconstruction can be managed with chronic uteteral stenting [86].

# Management of Stone Disease in Renal Transplant Kidneys

*Brian Duty & Michael Lam*

*Department of Urology, Oregon Health and Science University, Portland, OR, USA*

## Introduction

Over 870 000 individuals suffer from end-stage renal disease (ESRD) in the United States [1]. This number exceeds 2 million worldwide [2]. The majority of individuals being treated for ESRD live in affluent countries with robust healthcare systems and large elderly populations [3].

In 2009 more than US$40 billion was spent treating ESRD in the United States [1]. Despite comprising less than 1% of those covered by Medicare, patients with renal failure account for over 6.7% of the federal program's budget [1]. Between 2009 and 2010 the United Kingdom's National Health Service spent more on chronic kidney disease than on breast, lung, colon, and skin cancer combined [4].

Compared to dialysis patients, renal transplant recipients live longer (35.8 vs. 85.5% 5 year survival rate), and cost the healthcare system nearly three times less [1]. In the United States there are over 400 000 people on dialysis and a little more than 170 000 renal transplant recipients [1]. Globally, the majority of transplants are performed in Western Europe, the United States, and Australia [5].

Despite the survival and cost benefits, many transplant recipients experience urologic complications. A review of 1535 consecutive renal transplants in the United Kingdom found a urologic complication rate of 9.2% [6]. A more recent series reported similar results with 8% of 1670 recipients experiencing a urologic complication [7].

The two most common complications were urine leak and ureteroneocystostomy stenosis. While less common, allograft lithiasis is a potentially devastating postoperative complication. Most cases can be managed endoscopically, but treatment is frequently challenging due to the transplant's ectopic location and associated ureteroneocystostomy. This chapter will review the epidemiology, pathophysiology, clinical presentation, workup, and endourologic management of transplant stones.

## Epidemiology

A review of 2045 renal transplants from a single center found an allograft lithiasis incidence of 0.44% [8]. Mean time to presentation was 3.1 years following transplantation. A similar series of 1525 recipients reported an incidence of 0.46% [9]. A review of 42 096 transplant patients from the United States Renal Data System found a nephrolithiasis-associated hospitalization rate of 0.11% for men and 0.15% for women [10]. Female recipients were noted to be at increased risk of hospitalization for stone-related events compared to women within the general population.

Stones may be passed from the donor to the recipient at the time of transplantation (donor-gifted nephrolithiasis), or develop *de novo* after surgery. Donor-gifted nephrolithiasis is more common following deceased donor transplants as compared to living-donor transplants [11–13]. One explanation for this finding has been the traditionally low rate of imaging done prior to procurement. In a series of deceased donor renal transplants that underwent *ex vivo* ultrasound screening, the incidence of donor-gifted urolithiasis was found to be 0.64% [14].

In contrast, imaging is a fundamental component of the living donor screening process. Institutional variation exists but the following modalities have been utilized: renal ultrasound, computed tomography (CT) angiography, and magnetic resonance angiography. A consequence of this rigorous screening process has been the identification of nephrolithiasis in potential donors. A review of 377 individuals undergoing donor

Companion website: www.wiley.com/go/smith/textbookofendourology

evaluation with CT angiography found a 5% prevalence of asymptomatic renal stones [15].

Taking into account the increased utilization of CT to screen potential living donors, Kasiske and colleagues published guidelines in 1996 outlining selection criteria [16]. Nephrolithiasis was considered a relative contraindication to donation given the high risk of stone recurrence. However, the discrepancy between available donors and individuals suffering from ESRD has continued to widen over the past decade [17]. In an effort to address this shortage, some transplant organizations have developed less stringent guidelines to allow for "expanded criteria" deceased and "complex living" donors.

In 2004 more than 100 kidney transplant experts from over 40 countries met in Amsterdam to develop consensus-based guidelines meant to protect potential living donors [18]. Per the Amsterdam Forum, a potential donor with a single stone should undergo a metabolic workup including a 24 hour urine collection. In the absence of hypercalciuria, hyperoxaluria, hyperuricemia, cystinuria, or metabolic acidosis, donation may be considered. Contraindications to donation include infected stones and systemic disorders associated with increased recurrence rates such as inflammatory bowel disease, distal renal tubular acidosis (RTA), and sarcoidosis. The presence of multiple stones or nephrocalcinosis also preclude donation.

## Pathophysiology

A variety of surgical, pharmacologic, and physiologic factors promote *de novo* stone formation following transplantation. Technical factors include vesicoureteral reflux and ureteroneocystostomy stricture. Both complications promote stone formation by increasing the risk of urinary stasis and urinary tract infection (UTI). Foreign bodies such as persistent suture material or a retained ureteral stent also increase the risk of both infectious and noninfectious stones.

Immunosuppressive medications may also play a key role in *de novo* stone formation. Corticosteroids cause bone resorption, which has been associated with increased urinary calcium excretion [19]. Besides being nephrotoxic, calcineurin inhibitors (cyclosporine and tacrolimus) have been shown to induce hypocitraturia and hyperoxaluria [20]. In addition, cyclosporine has been demonstrated to cause hyperuricemia and gout [21].

ESRD is associated with a number of metabolic changes that promote stone formation. These may persist even after renal transplantation. Increased phosphorus levels along with parathyroid hormone resistance result in secondary hyperparathyroidism, which is associated with hypercalcemia, hypercalciuria, and hypocitraturia [22]. Up to 50% of individuals will continue to have persistently elevated parathyroid hormone levels (tertiary hyperparathyroidism) after transplantation [23]. This was confirmed in a series of 15 patients with allograft lithiasis who underwent a metabolic workup [24]. The authors found a 53% incidence of tertiary hyperparathyroidism.

Renal failure results in hyperuricemia because nearly 70% of uric acid is eliminated by the kidneys. Hyperuricemia may not resolve following transplantation for a number of reasons. As previously mentioned, cyclosporine is associated with hyperuricemia. Regardless, up to 55% of recipients not being managed with cyclosporine will have elevated uric acid levels [25]. The cause is not completely understood but graft dysfunction, diuretic use, male gender, diabetes mellitus, and obesity have been implicated [26]. The resulting hyperuricuria is not only a risk factor for uric acid stones but also calcium oxalate urolithiasis by heterogeneous nucleation.

Renal tubular acidosis following renal transplantation is common, with one study finding an incidence of 33% [27]. Type 1 RTA is most common, but type 2 and 4 RTA have also been reported [28]. Poor allograft function, calcineurin inhibitor nephrotoxicity, acute rejection, and ischemic tubular dysfunction have all been reported as causative factors [27]. Other potential etiologies include tertiary hyperparathyroidism, postoperative urinary obstruction, and UTI [29]. Type 1 RTA is associated with hypercalciuria and urinary alkalinization, which promote calcium phosphate stone formation.

## Presentation

Diagnosing an obstructive ureteral stone is relatively straightforward in the general population due to the classic signs and symptoms of renal colic. However, it is notoriously difficult in renal transplant patients due to denervation of the allograft during the harvesting process. Recipients rarely present with renal colic. In fact, more than half of recipients do not have any discomfort at the time of diagnosis [8, 30]. When present, patients usually report mild lower abdominal pain, which is believed to be due to peritoneal irritation from the hydronephrotic allograft. Collecting system dilation may be palpable on physical exam.

Most patients present with less specific signs and symptoms including decreased urine output, gross hematuria, recurrent UTIs, or urosepsis [11, 31, 32]. Acute renal insufficiency may be the only sign in some patients [33]. As a result, recipients with an obstructive stone may be misdiagnosed with acute rejection delaying appropriate treatment [34]. Fortunately, transplant nephrolithiasis does not appear to be associated with graft loss in the majority of those afflicted [35].

Time to presentation and subsequent diagnosis has been reported anywhere from 3 months to 18 years after transplantation [36]. However, a postoperative range of 1–4 years is more commonly cited [9, 11, 24].

## Workup

A high index of suspicion for allograft lithiasis must exist in recipients presenting with vague abdominal discomfort, hematuria, recurrent UTIs, or worsening renal function. Evaluation should begin with a detailed history and physical exam. The presenting complaint should be fully characterized along with a review of the recipient's immunosuppression regimen and other medical comorbidities. On exam the abdomen should be palpated to assess for evidence of allograft obstruction. Men with obstructive voiding symptoms should have a post-void residual performed to ensure adequate bladder emptying.

Laboratory testing should include a urinalysis (with microscopic exam and culture if indicated), complete blood count, and metabolic panel. Imaging should include either an ultrasound or CT. Ultrasonography may visualize a stone or show indirect signs such as hydroureteronephrosis (Figure 69.1). If obstruction is noted without an apparent cause, then a noncontrast CT scan should be obtained. CT should be the initial imaging study in patients presenting with severe signs and symptoms due to its higher sensitivity for urolithiasis and other urologic complications such as urine leak, lymphocele, or stricture (Figure 69.2).

Plain films should not be used as a primary diagnostic modality due to their low sensitivity for urolithiasis and inability to detect other surgical complications. If ultrasound or CT demonstrate an allograft stone, then consideration for obtaining an abdominal X-ray may be warranted to determine if the recipient is a potential candidate for shock-wave lithotripsy (SWL).

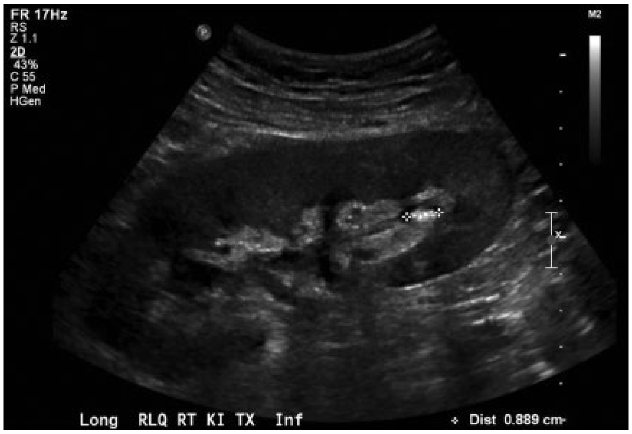

**Figure 69.1** Asymptomatic 8.9 mm lower pole allograft stone detected on annual renal ultrasound. Surveillance was elected. To date the stone has not enlarged or caused symptoms.

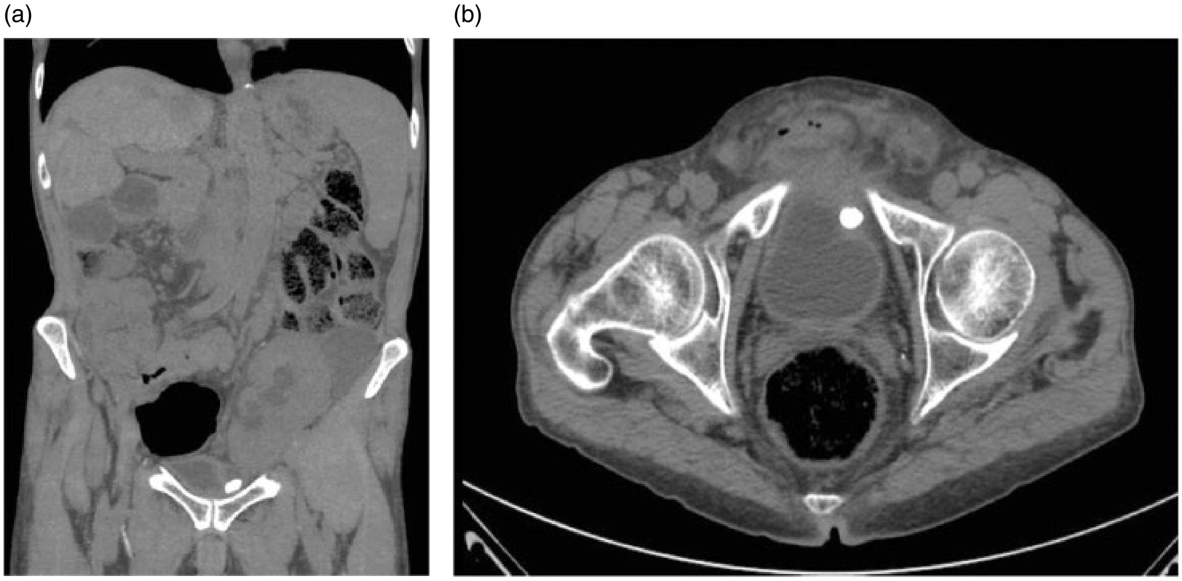

**Figure 69.2** CT images of allograft ureteral calculus measuring 12 × 9 mm at the ureteroneocystostomy site resulting in hydroureteronephrosis. (a) Coronal image. (b) Axial image. The stone was treated with antegrade ureteroscopy.

## Management

### *Ex vivo* ureteroscopy

Nephrolithiasis is no longer an absolute contraindication to kidney donation. Individuals with small stones and no significant metabolic abnormalities may be considered potential donors. Stones identified during the screening process can be treated prior to donation, during transplantation, or in the recipient after recovery. Treatment at the time of transplantation usually involves *ex vivo* flexible ureteroscopy (ExURS), but pyelotomy with flexible cystoscopy and stone extraction has also been described [37].

*Ex vivo* ureteroscopy has several potential advantages. It avoids the morbidity of an extra procedure for the donor prior to procurement, or for the recipient following transplantation. The kidney and ureter can be freely manipulated facilitating endoscopic access to the entire collecting system, which is not possible *in vivo* (Figure 69.3). One potential disadvantage of ExURS is increased cold ischemia time.

Once the kidney has been harvested it is transferred to the back bench and immediately flushed with cold preservation solution. ExURS is performed after the allograft has been prepared for implantation. If required, the ureteral stump is dilated or spatulated to allow passage of the ureteroscope. The allograft remains submerged in slush during the procedure and cold preservation solution is used for irrigation. The nondominant hand is used to manipulate the kidney to bring the stone-bearing calyx into a nondependent position. Small stones are basketed out of the collecting system. Larger stones are fragmented with the holmium laser and then extracted or irrigated out of the collecting system.

Only a few ExURS series have been published. In one series, 17 donors with stones ranging from 1 to 12 mm underwent ExURS with a 7.5 Fr flexible ureteroscope [15]. URS failed to visualize a stone in six cases and one allograft ureter did not accommodate the ureteroscope. ExURS was successful in the remaining 10 cases with five undergoing basket stone extraction, four laser lithotripsy, and one a combination of fragmentation and extraction. There were no stone-related complications. Mean treatment time was not reported.

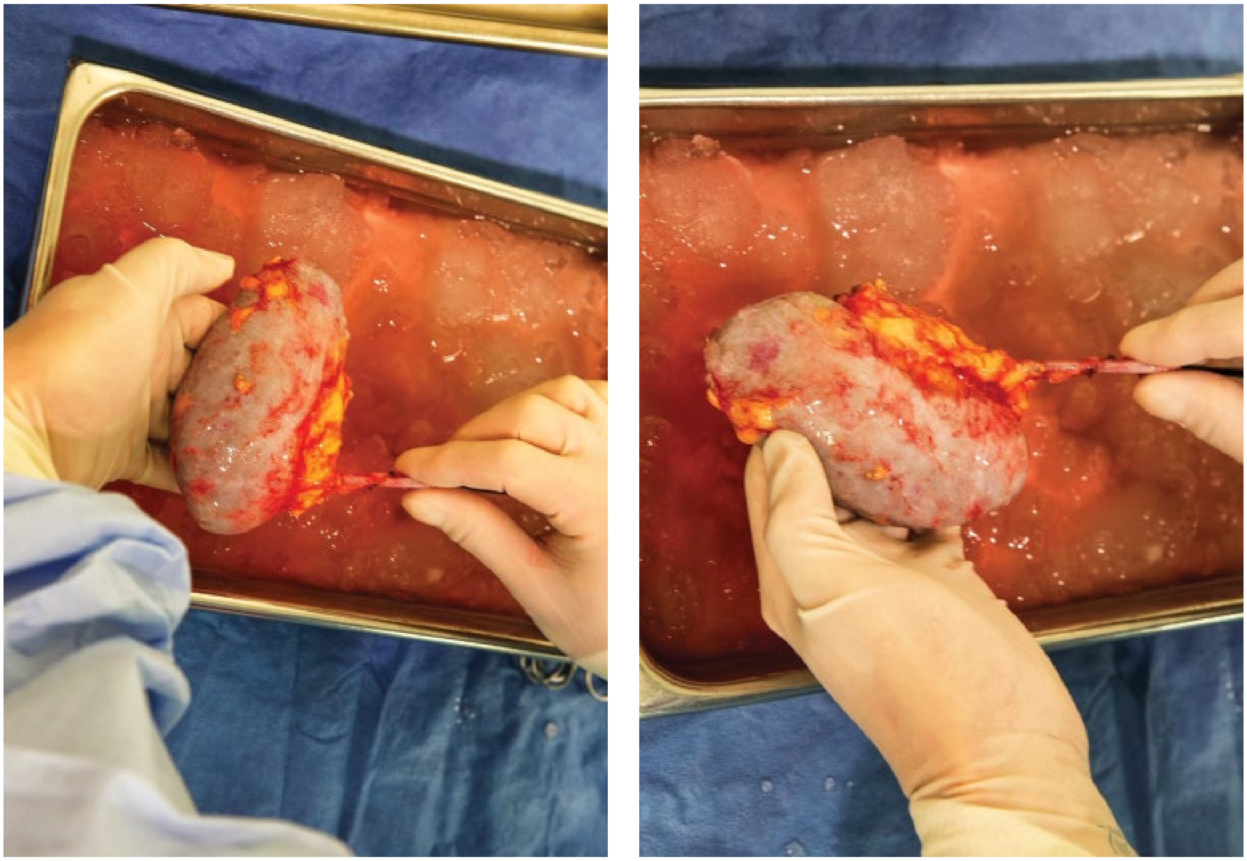

**Figure 69.3** Manipulation of renal allograft on the back bench to facilitate complete inspection of the collecting system during *ex vivo* ureteroscopy.

The largest series to date involved 28 stones in 23 allografts [38]. Mean stone size was 3.9 mm with a range of 3–6 mm. Stones were treated with either a 6.9 Fr semirigid or 9.5 Fr flexible ureteroscope. No stone was visualized in four cases. In the remaining 19 kidneys, 17 were rendered stone-free with basket stone extraction plus or minus laser lithotripsy. There were no intraoperative complications and mean treatment time was 6.2 minutes (range 3–10 minutes).

The most recently published series involved 14 donors with stones ranging from 4 to 10 mm in size [39]. Thirteen allografts were rendered stone-free without any intraoperative complications. Donors and recipients were followed up to 24 months and no graft dysfunction or stone recurrence were noted.

### Urgent decompression

Transplant recipients presenting with acute renal insufficiency or urosepsis from an obstructing stone require urgent urinary decompression with either a nephrostomy tube or ureteral stent. Pearle and colleagues performed a randomized study examining the optimal form of collecting system decompression in nontransplant patients with obstructing ureteral calculi and evidence of infection [40]. In this study of 42 patients, the authors found no clinical difference between the two forms of drainage, but nephrostomy tube placement was associated with a significant cost savings. An equivalent study has not been performed in transplant recipients.

Retrograde ureteral stent placement in transplant patients can be challenging for several reasons. The allograft ureter frequently inserts into the dome of the bladder at an oblique angle making ureteral orifice intubation difficult. In addition, the ureter is often redundant which promotes buckling of the stent during passage.

Ureteral stent placement may be contemplated in recipients who are relatively stable. However, nephrostomy tube decompression should be considered first-line treatment in patients presenting with urosepsis or renal failure with significant electrolyte abnormalities.

### Trial of passage

Transplant patients diagnosed with a ureteral stone may be managed conservatively in highly select cases. Oliguria, renal insufficiency, or evidence of infection are contraindications. Recipients with a history of medical noncompliance or stones greater than 4 mm are poor candidates.

There are no data to support the use of medical expulsive therapy in this setting. Patients should be counseled to watch for decreasing urine output. Close monitoring with weekly serum creatinine measurements and renal ultrasonography should be performed until the stone has passed or until surgical treatment is performed.

### Active surveillance

Intrarenal stones without evidence of obstruction may be managed conservatively provided the stone burden is negligible (generally less than 4 mm) and the patient does not have a history of recurrent UTIs. However, the recipient must be willing to undergo close observation given the risk of stone growth and graft obstruction.

In a study of 300 men with asymptomatic renal calculi followed for more than 3 years, clinical progression was noted in 77% of participants, with 26% undergoing surgical intervention [41]. Stone size was associated with risk of progression. Stones larger than 3 mm were 26% more likely to fail observation. In a similar study of 160 stones in 110 patients, 2% of patients developed painless hydronephrosis prompting surgical intervention [42]. This study highlights the need for radiologic surveillance given the risk of silent obstruction. Very little data exist regarding the safety of active surveillance in the transplant population. In a series from France spanning 30 years, 12 of 31 patients with asymptomatic allograft stones elected to undergo surveillance [13]. Two patients spontaneously passed their stone and the remaining 10 experienced no stone-related events or stone growth.

Spontaneous passage rates have largely been reported in surgical treatment series rather than studies evaluating the feasibility of active surveillance. Challacombe et al. reported a 9.5% passage rate (two of 21 patients) [11]. Similarly, Mamarelis and colleagues reported spontaneous stone passage in two of nine patients [8]. Other studies have reported higher passage rates (38 and 60%, respectively) for stones less than 4 mm in size [43, 44].

Recipients electing to undergo active surveillance must understand that there are little data to support its safety in the transplant population. Additionally, they must comply with close radiologic surveillance (annually at minimum). Metabolic testing with results-directed therapy should also be instituted to decrease the risk of stone progression.

### Surgical treatment

There are no practice guidelines or level 1 data governing treatment of allograft stones. As a result, treatment decisions are generally dictated by stone burden, location, and provider skillset. Surgical options include SWL, ureteroscopic lithotripsy, and percutaneous nephrolithotomy (PCNL). Percutaneous treatment is generally recommended for stones larger than 1.5 cm in diameter, whereas SWL and URS are utilized for smaller stones.

## Shock-wave lithotripsy

SWL has the advantage of being the least invasive treatment option. Factors unique to the transplant population include overlying bowel gas and location adjacent to the bony pelvis, which makes stone localization more difficult. This may account for the high failure and retreatment rates reported by some authors.

In a small series, Verrier et al. reported a 50% (two out of four patients) failure rate [13]. However, one of the patients who failed treatment had a stone larger than 1.5 cm in size. A recent article from Yuan et al. reported successful treatment in four of five patients [45]. In two series, each with seven patients, Klinger et al. and Li et al. reported 100% success treating stones between 0.4 and 1.1 cm [21, 37].

It should be noted that the definition of treatment success has not been uniformly defined across studies. It is common for patients to be considered successfully treated despite requiring multiple SWL sessions to achieve stone-free status. Li et al. reported patients needing anywhere from one to three sessions, and Yuan et al. reported two to four sessions per patient [21, 45]. Eight of 13 subjects required retreatment in a series reported by Challacombe et al. [11]. Roughly 60% of patients treated with SWL will require multiple sessions [46]. In addition to retreatment, adjuvant procedures are often required, which include ureteral stent and nephrostomy tube placement [11].

There have been no studies comparing prone versus supine positioning in SWL for transplant lithiasis. Several studies claim prone positioning allows for better stone visualization on fluoroscopy, which may improve stone-free rates [11, 37].

Following treatment, recipients must be closely monitored for steinstrasse (serial blood work and imaging) given the presence of a solitary, denervated renal unit. There is no consensus on preoperative ureteral stent or nephrostomy tube placement. However, placement should be strongly considered in patients with significant stone burdens (greater than 1 cm). Nephrostomy drainage is usually recommended for recipients with obstruction from stone debris after SWL as retrograde access is unreliable in the transplanted ureter [37].

## Ureteroscopy

Flexible URS has several potential advantages over SWL. It permits finer control over stone fragmentation and has the potential for stone extraction. However, URS is technically more challenging than SWL due to the altered ureteral and renal anatomy.

Retrograde ureteroneocystostomy access is often difficult because the allograft ureter frequently inserts obliquely into the dome of the bladder. Use of a 70° lens, angled access catheters, and the Albarran cystoscope bridge deflector are often required to promote wire passage. Sevinc and colleagues recently described using the semirigid ureteroscope to facilitate identification and access of the allograft ureter [12].

Variations in ureteroscopic treatment options exist in patients with previously placed nephrostomy tubes. The nephrostomy tube may be used to direct a wire down the ureter into the bladder to facilitate retrograde URS. Alternatively, nondilated antegrade URS with or without ureteral access sheath placement can also be performed [47].

Success rates for URS vary, and available studies are limited. In the largest series to date, Basiri et al. reported a success rate of 72% in 13 of 18 patients who underwent URS for either stones or retained stents from 1989 to 2002 [48]. In those treated for calculi, 67% were rendered stone-free. Verrier et al. reported a 67% success rate in three of five patients [13]. More recent studies have reported greater success, perhaps owing to improvements in flexible ureteroscope technology. Yuan et al. utilized flexible retrograde URS successfully in four patients, rendering all stone-free, in calculi up to 1 cm in size [45]. In a cohort of 11 patients from 2006 to 2011, Hyams et al. were able to render 10 recipients stone-free after a single procedure [47]. Five patients in this study had pre-existing nephrostomy tubes that were used for antegrade URS. Lastly, Sevinc and colleagues published a series consisting of five recipients with a mean stone size of 0.9 cm that were rendered stone-free [12].

Complications in patients undergoing URS include hematuria, UTI, pyelocutaneous fistula, ureteral perforation, and stricture [12, 45, 47, 48]. The allograft ureter lacks soft tissue support and is frequently redundant, increasing the risk of perforation during ureteroscope passage and lithotripsy. In one older series, Del Pizzo et al. successfully treated six of seven patients with small distal ureteral stones with semirigid URS [32]. However, one patient suffered a ureteral perforation. Yuan et al. reported ureteral perforation in one of five patients undergoing retrograde flexible URS, requiring an indwelling stent for 2 months [45]. The use of a safety wire with an extra stiff core should be strongly considered, and the bladder should be completely emptied prior to scope passage to minimize the risk of ureteral perforation. In addition, semirigid URS should be avoided in the majority of cases.

## Percutaneous nephrolithotomy

PCNL is the most commonly described allograft lithotripsy modality. It was first reported in 1982 by Fisher and colleagues [49]. Following partial chemolysis, a uric acid stone was extracted with a basket through a percutaneous tract. Three years later Hulbert et al. reported a more traditional PCNL approach with dilation of a percutaneous tract up to 28 Fr to facilitate insertion of an access sheath [50]. At present, PCNL is generally recommended for stones larger than 1.5–2 cm and is thought to have the highest single-procedure stone-free rate [7, 9, 51].

As opposed to traditional PCNL where patients are commonly placed in the prone position and access is obtained through a posterior calyx, percutaneous treatment of allograft stones is performed in the supine position with access through an anterior calyx. Access may be gained under fluoroscopic or ultrasonic guidance. If fluoroscopy is utilized, preoperative imaging is essential to rule out overlying bowel. Many patients will have an existing nephrostomy tube placed by interventional radiology due to obstruction at the time of presentation. However, depending on stone location, patients may require a second puncture to facilitate stone treatment. Once access has been obtained, a sheath is placed using either a balloon dilator or sequential dilators. Tract dilation is oftentimes more difficult due to fibrous encasement of the transplanted kidney. Treatment of the stone then proceeds via a variety of mechanisms: direct extraction, ultrasonic, pneumatic, or holmium laser lithotripsy. A combination of flexible cystoscopy and URS can aid in repositioning as well as treating stones that are difficult to reach with the rigid nephroscope.

In a series of 13 patients treated percutaneously, 77% had complete stone clearance after a single procedure [7]. The remaining three patients underwent second-look nephroscopy on postoperative day 1 for residual stone. In another series, all seven patients who underwent PCNL were rendered stone-free after one procedure [52].

Complications reported after PCNL include bowel perforation, bleeding, urinary or arteriovenous fistula formation, herpes esophagitis, urinoma, and impaired wound healing [11, 45, 52]. Transplant patients are at particularly high risk due to immunosuppression. As a result, many centers avoid PCNL in the perioperative period due to higher immunosuppresive medication requirements [11]. Multiple studies have demonstrated stable renal function over long-term follow-up [7, 45].

As of late, minimally invasive PCNL (mini-PCNL) has been increasingly utilized in both traditional as well as transplant lithiasis. Using a smaller access tract may reduce blood loss by minimizing parenchymal injury and allowing for greater intrarenal maneuverability with less tissue shearing. In the general population mini-PCNL has been associated with decreased blood loss and less postoperative pain despite longer operative times [53]. A recent case report from Croatia used a 12 Fr mini-nephroscope through a 15–16 Fr sheath to successfully treat an allograft renal pelvis stone [46]. The largest series in the transplant literature involved 11 recipients who underwent tract dilation between 14 and 18 Fr [54]. All eleven patients were rendered stone-free after a single procedure. He et al. reported an overall operative time of 53 minutes among seven patients who were successfully treated with mini-PCNL [55]. Only one patient experienced a postoperative complication (recurrent UTIs).

### Open surgery

Thanks to technological advances in minimally invasive stone treatment, open approaches are increasingly rare and are now generally only indicated when all other therapies have failed, or when open repair of another urologic complication (e.g., ureterovesical stricture) is required. Open lithotomy procedures are associated with more pain, longer recovery and increased risk of major complications due to dense adhesions around the grafted kidney and ureter.

## Conclusion

Transplant nephrolithiasis represents a rare but challenging entity for clinicians. The diagnosis is often challenging to establish due to allograft denervation, which can delay treatment resulting in graft injury or loss. However, once the diagnosis is made, treatment is usually successful using traditional minimally invasive therapies such as SWL, URS, and PCNL. Choice of treatment remains largely based upon stone burden and location, and each modality has its own nuances and challenges.

# Stones in Urinary Diversions

*Bodo E. Knudsen & Michael W. Sourial*

*Department of Urology, The Ohio State University Wexner Medical Center, Columbus, OH, USA*

## Introduction

Urinary diversion using intestinal segments is a widely employed technique in reconstructive urology for the care of urologic patients with both benign and malignant diseases. Applications include pediatric urology, neurogenic bladders, reconstructive urology, and oncology. A wide range of urinary diversions have been described; however, the ileal conduit and the continent orthotopic neobladder are the two of the most commonly performed urinary diversions at present.

Urinary diversions have posed unique challenges to the urologist. Long-term complications include renal insufficiency, recurrent infections, strictures, metabolic and electrolyte disturbances, secondary malignancies, and calculi. Although modifications and improvements in surgical technique have reduced the risk of complications, postsurgical problems still occur. One such complication is the development of calculi in the diversions. While open surgical management has played an important role in the management of this problem, the advent of endourology and minimally invasive surgical techniques have helped reduce the morbidity from the surgical management of stones in these patients. (See Video 70.1).

## Etiology

The etiology of stone formation in patients with urinary intestinal diversion is multifactorial. These can be classified mainly as idiopathic, metabolic, infectious, or structural. It is well known that patients with urinary diversion have metabolic abnormalities due to the reabsorption of urinary solutes across the intestinal mucosa. Hypercalciuria secondary to hyperchloremic metabolic acidosis is a predisposing factor for calcium phosphate stones. In a study by Terai et al., hypocitraturia was observed in over one-third of patients. An increase in excreted calcium and phosphate coupled with an increase in urine pH created a favorable milieu for infectious calculi [1]. Further, these patients are also often dehydrated, contributing to the process of stone formation.

Patients with urinary diversion are often colonized with urease-producing bacteria. Common uropathogenic organisms cultured include *Proteus*, *Klebsiella*, and *Pseudomonas* [2], which metabolize urea into ammonium and bicarbonate. The alkaline milieu predisposes to infectious stones, including struvite, carbonate apatite, and ammonium acid urate stones.

Other risk factors for stone formation include excessive mucous production by the intestinal mucosa [3], foreign bodies (staples, nonabsorbable sutures, etc.) acting as a nidus for stone formation, urinary stasis in patients who incompletely empty their reservoirs, or obstruction. Irrigation of the reservoir may be helpful in reducing stone formation by clearing bacterial load and mucous deposits [4–6].

## Rates of stone formation

The reported incidence of stones varies depending based on the type of urinary diversion. The incidence of stones is 11–12% in patients with an ileal conduit [7, 8]; 17–43% in patients with a Kock pouch [4, 9, 10]; and 11–19% in patients with an Indiana pouch [10, 11]. Abol-Enein and Ghoneim [12] published their experience with 450 patients having undergone an orthotopic ileal W-shaped neobladder with serous-lined extramural ureteral reimplantation. Their stone incidence rate was 3% [12]. Ferriero et al. reported a rate of neobladder stone formation of 9.2% in 445 consecutive patients who underwent radical cystectomy and a non-absorbable, titanium

stapled orthotopic neobladder [13]. Overall, the incidence of stone formation in patients with urinary diversion seems to be decreasing, due in part to use of absorbable surgical material, and also the heightened awareness of the metabolic and infectious causes of stone formation [14].

The recurrence rate of stones in patients with urinary diversion is common, with reports suggesting rates as high as 50–63% over 5 years [15, 16]. Recurrent urinary tract infection appears to be a risk factor for stone formation [5, 15]. The rate of recurrence seems to be independent of the treatment technique and patient characteristics [16, 17]. Patients with infectious stones may also have recurrences with other non-infectious type of stones [18].

## Types of stones

Patients with urinary diversion are predisposed to infectious stones due to the frequent colonization of the intestinal segment with urease-producing bacteria. These will hydrolyze urea into the bicarbonate and ammonium. Excess bicarbonate in the urine creates an alkaline urine pH, and leads to the formation of magnesium ammonium phosphate and carbonate apatite stones. Additionally, the hyperchloremic metabolic acidosis state often seen in patients with ileal conduits or colonic reservoirs results in decreased reabsorption of calcium and a decreased production of citrate by the kidneys, favoring calcium stone formation. Calcium oxalate stones are also not infrequently seen in patients with urinary diversion. Hyperoxaluria may be seen in patients when small bowel, especially the terminal ileum, is used for the reconstructive procedure. Resection of the terminal ileum results in an increase in unabsorbed fatty acids and bile salts which undergo saponification by binding with calcium in the bowel. This leads to an increase in unbound oxalate which is absorbed by the large intestine and subsequently excreted in the urine. The resultant hyperoxaluria favors the formation of calcium oxalate stones. In a study by Hertzig et al., the stone composition in 77 patients having undergone a radical cystectomy and ileal conduit was reported. The vast majority (63.5%) were magnesium ammonium phosphate stones, with the remainder being 25% calcium phosphate, 9.6% calcium oxalate monohydrate, and 1.9% calcium oxalate dihydrate [19].

## Surgical management

The surgical approach should take into consideration the location and size of the stone and the anatomy of the diversion to plan the access route. Open surgical extraction has been largely replaced by endoscopic and minimally invasive surgical techniques. Modalities such as extracorporeal shock-wave lithotripsy (ESWL), antegrade and retrograde ureteroscopy, trans-stomal lithotripsy, percutaneous nephrolithotomy, and percutaneous transreservoir lithotomy have been described in the literature.

### Stones in the urinary diversion

Stones in the intestinal diversion may be managed by endoscopic or open techniques. The anatomy of the urinary tract and also the surrounding structures should be outlined with prior radiographic imaging, typically noncontrast computed tomography (CT). Any concomitant strictures should also be delineated and will likely also need to be addressed. Access to the diversion is most easily obtained through the stoma, especially for patients with ileal conduits. In patients with continent reservoirs, care should be taken to avoid traumatizing the continence mechanism. In-and-out access through the continence mechanism should only be used for patients with minimal stone burden, with care to avoid excessive manipulation to prevent postoperative leakage or strictures. A flexible cystoscope can usually be safely passed into most diversions, including an Indiana pouch. Olympus produces a flexible cystoscope that has a suction channel. This can be very helpful as it allows the reservoir to be suction-irrigated, allowing for the clearance of mucus and some debris (see Figure 70.1). In patients with orthotopic reservoirs, access through the urethra with rigid instruments is feasible, although there is a risk of bladder neck contracture. Fragmentation of the stone can be performed with a holmium:YAG laser, ultrasonically, pneumatically/ballistically, or with an electrohydrolic lithotripter. Ultrasonic lithotripters are increasingly being used as they are less harmful to the intestinal mucosa [20].

The use of ESWL in patients with a Kock or Indiana pouch has been reported in a small number of patients. These patients should undergo pouchoscopy to ensure the absence of staples or other foreign material acting as a nidus for stone formation. In addition, basketing of fragments is probably necessary to render these patients stone-free [14, 20, 21].

Percutaneous access has become the technique of choice in patients with a large stone burden in their reservoir. The Amplatz dilator system or balloon dilation, with a large 24–30 Fr working sheath, allows for larger instrumentation use and facilitates stone removal. Access can be directly visualized with a flexible cystoscope placed through the stoma site. Deflection of the endoscope to transilluminate the abdominal wall may help in obtaining the optimal access site. A CT scan to outline

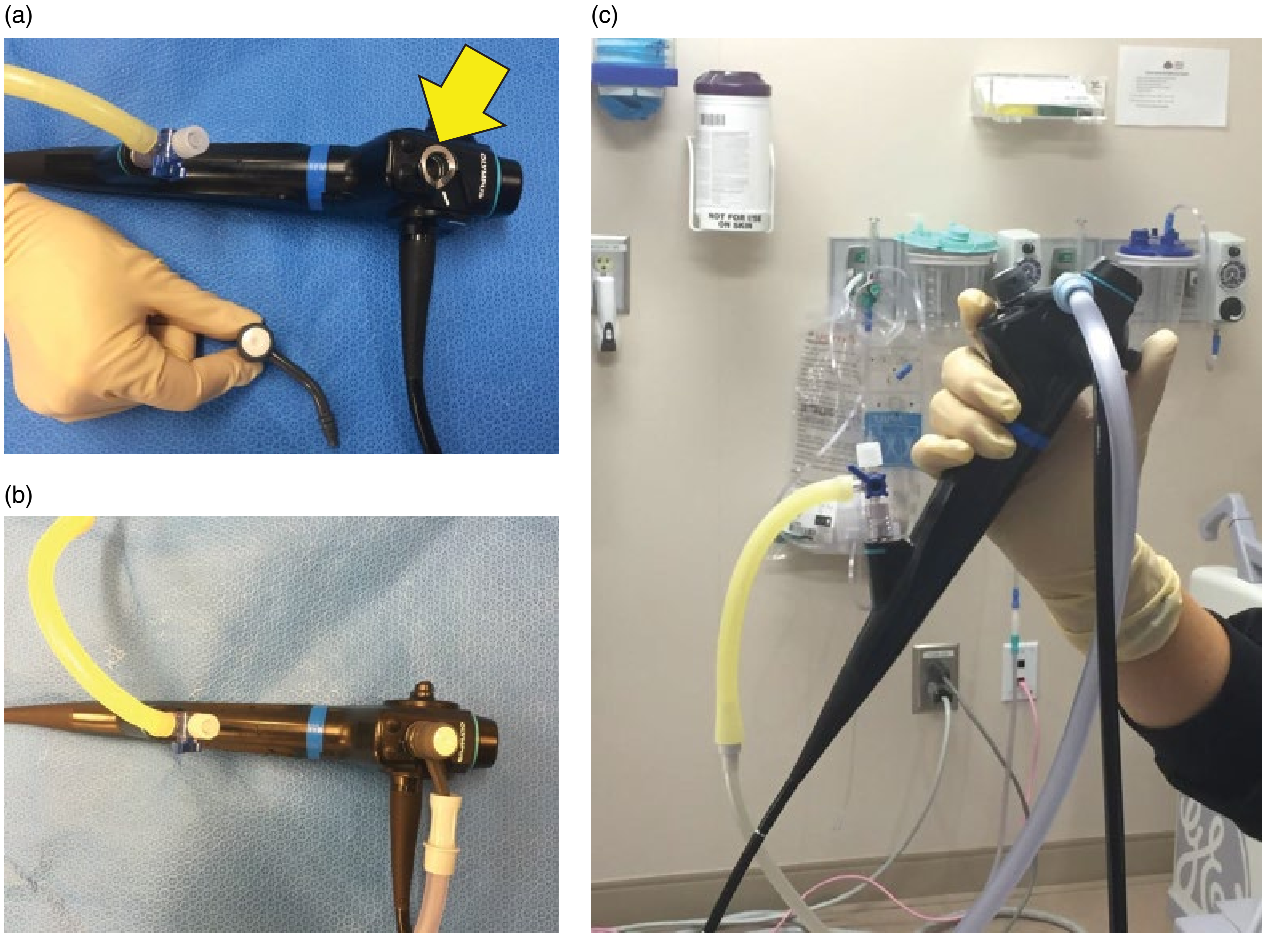

**Figure 70.1** Olympus cystoscope with suction adapter. The adapter fits on the head of the cystoscope and can then be plugged into the usual suction apparatus.

the surrounding anatomy is crucial in these cases to avoid adjacent organ injury. A handheld ultrasound at the time of puncture can also facilitate a safe puncture and avoid adjacent structures such as the bowel. Stones as large as 5 cm have been removed using this technique [22–24]. Breda et al. published the largest known series using exclusively the percutaneous approach in 74 pediatric patients with a reconstructed bladder. Their mean stone size was 2.4 cm (range 1–4.7 cm), and the mean number of stones was 4.6 (range 1–60). Their mean operative time was 96 minutes. The reported stone-free rate was 95% at 2 weeks using a simple abdominal X-ray as imaging. Overall complication rate was 12%, and included infection, difficulty catheterizing the Mitrofanoff channel, and encrustation of the catheter used for drainage [25]. Paez et al. reported their series of percuatenous access in 12 patients with no observed complications. Although stone clearance was achieved in all 12 patients initially, stone recurred in five patients at a median follow-up of 24 months [26].

A combination of endoscopic and laparoscopic instruments may also be used for larger stone burden. After obtaining percutaneous access, stones can be placed in an endocatch bag brought into the reservoir via either the primary access [27] or a secondary access [28]. The endocatch bag is then removed altogether by widening the skin incision, or the stones can fragmented within the bag to reduce intestinal mucosal injury and the loss of small fragments. In their series of eight patients, Lam et al. [27] reported a mean operative time of 123 minutes. The mean stone size was 4.1 cm (range 1.5–7.0 cm), and six of the eight patients had multiple stones. All eight patients were rendered stone-free, and there were no complications. This procedure was done on an outpatient basis, or patients were discharged within 23 hours of surgery.

Open cystolithotomy has fallen out of favor due to efficient and less morbid minimally invasive techniques, and is typically reserved for patients with a very large stone burdens or in centers that lack specialized equipment for a minimally invasive approach. Although there have been no published reports in the literature, pure laparoscopic or robotic cystolithotomy can be considered in experienced hands as an alternative to the open technique [23].

### Stones in the kidney (5 mm or less for expectant treatment) and ureter

Similar to patients without urinary diversion, small symptomatic stones <10 mm may be managed expectantly initially if the pain is well controlled and there is no evidence of infection. The addition of an alpha-blocker to promote stone passage may be considered, although its efficacy in patients with urinary diversion has not been studied. There should be a lower threshold for definitive management of the stone in these patients since a large proportion are colonized by various organisms, and are probably at higher risk of developing an infection. ESWL remains a good initial management option in patients with smaller stones, and avoids the difficulties of obtaining access. The reported success rates of ESWL in patients with urinary diversion range from 25 to 92% [19, 29–32]. Preoperative urine culture should be obtained on all patients prior to treatment, and patients should be treated with appropriate antibiotics when indicated to reduce bacterial colony count. In patients with an orthotopic or continent catheterizable reservoir, pouchoscopy should be considered post-ESWL to ensure that no residual fragments are lodged between the mucosal folds.

Both retrograde and antegrade endoscopic approaches have also been utilized to treat stones in patients with urinary diversions. The main difficulty in this group of patients is finding the neo-ureteric orifices to obtain ureteral access for retrograde access. Difficulty distending the conduit, mucosal folds, and bowel tortuosity can make it challenging to find the neo-ureteral orifices. Hyams et al. published the largest known series of retrograde access in 28 patients with urinary diversion, with a success rate of 90% for orthotopic neobladders, 73% for ileal conduits, and 33% for Indiana pouch patients [33]. Intravenous injection of methylene blue may help to identify the neo-ureteral orifices. Detailed knowledge of the diversion procedure is also critical, although at times that information may not be available depending on when and where the diversion was performed. Knowing the type of ureteral implant (i.e. Bricker, Wallace, etc.), as well as the location of the ureteral implantation (i.e. at the end of the conduit, at the side of conduit) may help in localizing the neo-ureteral orifices. For an antegrade approach, ultrasound-guided access may be used to insert a finder needle and perform a nephrostogram under fluoroscopy to identify the best calyx for the approach [23]. Percutaneous nephrolithotomy remains the standard of care for patients with large stone burden. Once the proper calyx is punctured, dilation of the tract and the formal procedure is then carried out in the same fashion as for patients without a urinary diversion. For smaller stones in the ureter, an antegrade ureteroscopy can be performed with minimal dilation. At our institution we have passed a short 12/14 Fr ureteral access in an antegrade fashion to facilitate the passage of a flexible ureteroscope to treat ureteral stones (see Figure 70.2). The advantage of using the sheath is that it facilitates multiple passes and extraction of the stone fragments.

## Prevention

### General strategies

Due to the very high recurrence rate of stones, preventative measures are of pivotal importance in this group of patients. Patients should be counseled on appropriate dietary measures, including an adequate fluid intake to produce >2 L of urine per day. These patients should have two 24 hour metabolic workups to identify and potentially treat any metabolic abnormalities [34]. Proper emptying of the reservoir should be confirmed. Regular voiding or catheterization schedule should be encouraged to avoid urinary stasis while maintaining a low residual volume. Surgical strategies to prevent stones include using absorbable material and ensuring that nonabsorbable materials are not exposed to urine.

Mucous appears to play a role in the formation of stones in the reservoir, and there may be a benefit at irrigating a reservoir to clear the mucus [3]. Hensle et al. noted a significant decrease in stone formation after instituting a strict irrigation protocol consisting of twice-weekly irrigation of saline (240 mL) and once-weekly gentamicine sulfate solution [6]. Irrigation using 20% urea solution has also been described for refractory cases [5]. Terai et al. noted a 12% risk of stone formation in Japanese patients with an Indiana pouch, compared to 5.4% for US patients. The only difference noted was that patients in the United States were placed on a standard irrigation protocol [4].

### Noninfectious stones

Predisposing metabolic abnormalities need to be identified and corrected. Hypovolemia must be addressed if present. Hyperchloremic metabolic acidosis and the resulting hypocitraturia seen in about one-third of patients can be corrected with oral citrate supplementation. Calcium oxalate stone-formers with enteric hyperoxaluria may benefit from restricting high-oxalate-containing foods combined with higher calcium intakes, which may

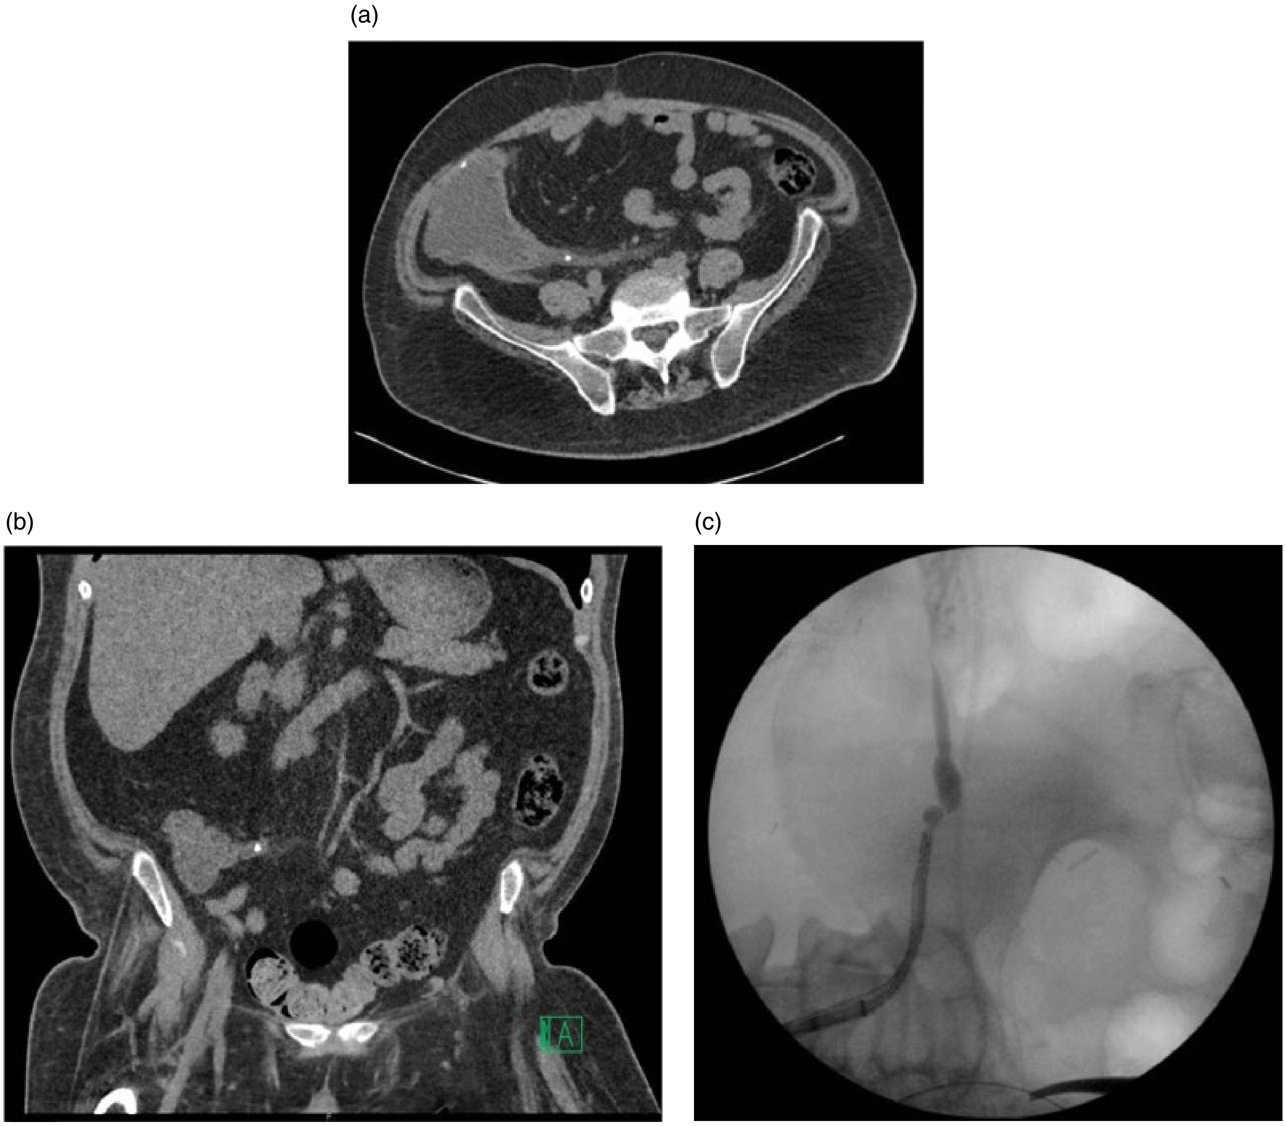

**Figure 70.2** (a, b) Axial and coronal CT images of a patient with an Indiana pouch, found to have a left 4 mm obstructing ureteral stone. (c) Intraoperative fluoroscopy during antegrade ureteroscopy using a 12–14 Fr access sheath.

include supplements, specifically timed with meals. The calcium will bind to oxalate in the gastrointestinal tract, preventing it from being absorbed [34], as indicated.

## Infectious stones

In patients with struvite stones who are colonized or infected with urease-producing organisms, antibiotic therapy is indicated, particularly in the case of recurrent stones. Oral prophylactic measures for struvite stones also include acetohydroxamic acid, an irreversible urease inhibitor. Its extensive side effect profile, particularly phlebitis and other hypercoaguable events, limits its use. Chemodissolution therapy for residual struvite fragments includes hemiacidrin or Suby's G solution. Hemiacidrin reached its pinnacle of publications between 1973 and 1988, with its use described through nephrostomy tubes after pyelolithotomy (open, minimally invasive surgery, or SWL), through ureteral catheters for chronically ill or spinal cord patients, and even as primary therapy through nephrostomy tubes, with complete responses (>75%) reported in most series. Hemiacidrin's shortcomings far outweighed its advantages, and this therapy has declined due to several reasons, namely its cost, intense irrigation protocol (requiring instillation at low renal pelvic pressures), prolonged immobility (requiring deep-vein thrombosis prophylaxis), and hospitalization required to monitor its administration, and the advent of more effective minimally invasive therapy [35]. Hemiacidrin has been shown to be safe and effective in patients with an ileal conduit [36].

## Conclusion

The management of stones in patients with urinary diversion is a common occurrence and something that most endourologists will need to manage. The metabolic, infectious, and structural risk factors to stone formation should be elucidated and corrected to prevent stone formation and recurrence in this high-risk population. Prophylactic measures to reduce stone recurrence rate should be considered in all patients. The advent of endourology and minimally invasive techniques has facilitated stone retrieval in these patients while considerably minimizing morbidity, although unique challenges to these procedures remain.

## Introduction

Recent data from epidemiological studies suggest that the prevalence of overweight and obese individuals has significantly increased over time from 15 to 35.04% in men and 36.84% in women in the United States [1]. Obesity is a major public healthcare problem, and generally accompanies with comorbid conditions such as hypertension, diabetes mellitus, hyperlipidemia, hypercholestrolemia, and cardiovascular disease. The body mass index (BMI) is an objective measure of obesity and patients with a BMI greater than 40 kg/m$^2$ have an extremely high relative risk of comorbid diseases [2]. Additionally, large population-based studies have shown that obesity and weight gain increase the risk of kidney stone formation caused by alterations of urinary metabolite excretion in adults [3, 4]. In a cross-sectional analysis of the National Health and Nutrition Examination Survey (NHANES), the prevalence of urolithiasis was 11.2% in obese individuals [5]. Based on prevalence and cost estimation for 2030, obesity and diabetes will independently increase stone prevalence by 0.36% and 0.72%, respectively, and the cost of urolithiasis is projected to increase to an additional US$1.24 billion/year [6]. The management of obese stone formers has become safe and more effective owing to advances in minimally invasive techniques and improvements in anesthesia, but in this group of patients there may be encountered some specific technical challenges that the urologist needs to be aware of to provide optimum care.

In this chapter we discuss obesity and stone risk, covering urine pH, hyperinsulinemia, metabolites, and inhibitors, followed by weight-loss diets and the risks of stone disease after bariatric surgery. We then cover medical therapy in obese stone formers followed by the interventional therapies available: shock-wave lithotripsy, ureterorenoscopy, and percutaneous nephrolithotomy.

## Obesity and stone risk

Studies showed that the most common stone component in obese patients is calcium oxalate and a slightly higher incidence was found of uric acid stones as well [3, 7]. In addition, the authors suggest that obesity is strongly associated with an increased risk of stone episodes. In an effort to elucidate possible urinary changes, a lot of studies have been conducted and several factors have been found to be involved in stone formation in obesity.

### Urine pH

Urinary pH is one of the important factors of stone formation. Li et al. demonstrated that urine pH is inversely related to BMI among obese patients with urolithiasis [8]. They found that the mean urine pH of normal body weight, overweight, and obese groups was 6.25, 6.14, and 6.00, respectively. Hyperinsulinemia, insulin resistance, and gout diathesis may be the factors which cause lower urinary pH in obesity.

### Hyperinsulinemia

Obese patients have a higher incidence of diabetes mellitus which is correlated with hyperinsulinemia or insulin resistance. Insulin is known to stimulate the synthesis of ammonia and sodium–hydrogen exchange in the renal tubule which mediates ammonium excretion in urine. Hyperinsulinemia associated obesity contributes

Companion website: www.wiley.com/go/smith/textbookofendourology

to the development of calcium stones by decreasing urinary citrate and increasing urinary excretion of calcium, uric acid, and oxalate [9]. Insulin resistance may be linked to defective ammonium production and the ability to excrete acid, and may cause lowered urine pH. Cameron et al suggested that increased incidence of uric acid stone formation in patients with diabetes may be secondary to production of more acidic urine than in non-stone-bearing counterparts [10].

## Metabolites

High metabolic load is another important factor for urolithiasis in obesity. Powell et al. demonstrated that increased urinary concentrations of sodium, oxalate, uric acid, phosphate, and cystine were found in obese patients compared with non-obese counterparts and these urinary changes mostly appeared in obese women [3]. Taylor and Curhan stated that male obese patients excreted more urinary oxalate, calcium, uric acid, sodium, and phosphate than non-obese patients. Women obese patients also excreted more urinary oxalate, uric acid, sodium, and phosphate than non-obese patients, but increased urinary calcium was seen only in younger women. An inverse relation between BMI and urine pH was seen also in both men and women [11].

Fructose consumption has markedly increased over recent decades owing to widespread use of high-fructose syrup. Taylor and Curhan reported that high levels of fructose intake were associated with increased relative risk of stone formation regardless of BMI, caloric intake, or other risk factors [12]. The mechanisms underlying the relationship between fructose and stone risk are unknown, but may be related to the effect of fructose intake on urine composition. Fructose intake may alter calcium metabolism, particularly in the setting of low magnesium intake. In contrast, Knight et al. demonstrated there was no change in 24 hour urine calcium, oxalate, or uric acid excretion with increasing fructose consumption [13].

The level of physical activity and energy intake may increase risk of stone formation. An observational study reported that among postmenopausal women, increased levels of physical activity and lower energy intake were associated with a significant reduction in the risk of kidney stones, even after taking into account BMI, history of diabetes, and intake of fluid, dietary calcium, sodium, and animal protein [14]. However, a recent study from three large prospective cohorts, the Health Professionals Follow-up Study (HPFS) and Nurses' Health Studies (NHS) I and II, concluded physical activity and total energy intake were not independent risk factors for kidney stones [15].

## Inhibitors

Urinary citrate excretion is determined by acid/base status related to the intracellular pH of renal proximal tubule cells [16]. Acid load promotes proximal tubular reabsorption of citrate and reduced citrate synthesis. Lowered urinary pH is commonly seen in obese patients which leads to hypocitraturia. Magnesium complexes with oxalate, thereby potentially reducing oxalate absorption in the gastrointestinal tract. Consequently, high metabolic load and decreased excretion of inhibitors such as citrate and magnesium facilitate urolithiasis in spite of increased urinary volume [17].

Regarding the negative effects of comorbid disease and urolithiasis on kidney function together with limitations of stone surgery, the medical management of stone disease seems to be the most important goal for preventing further recurrences in morbidly obese patients.

## Weight-loss diets

Weight-loss diets have gained popularity since preventative measures for disease have been shown to reduce healthcare expenses in developed countries. Most dietary fads include low-carbohydrate, high-protein, and/or high-fat diets (e.g. the Atkin's diet, Ducan's diet, South Beach diet, and Sugar Busters diet). These kinds of diet deliver a significant acid load to the kidney, which might increase the risk of stone formation and bone loss. Despite there being no concrete evidence to link stone formation with such diets, addition of alkali therapy may reduce acidosis and hypercalcuria, and normalize citrate metabolism. Taylor et al. concluded that a diet high in fruit and vegetables, and low in animal protein, is associated with reduced risk of stone formation [18].

## Stone disease after bariatric surgery

Use of surgical procedures for obesity (bariatric surgery) has risen over the past two decades. A worldwide survey study performed in 2011 demonstrated that Roux-en-Y gastric bypass (RYGB) for restrictive and malabsorptive surgery made up 46.6% of weight-loss procedures, followed by sleeve gastrectomy (27.8%) and adjustable gastric banding (17.8%) as restrictive surgery [19]. Although such procedures effectively manage obesity-dependent comorbidities, a large controlled study revealed that the patients who underwent RYGB surgery had approximately two times higher risk of nephrolithiasis than obese patients [20]. In patients who have undergone bariatric surgery, fat malabsorption leads to hyperabsorption of oxalate, which is exacerbated by an increased permeability of the gut to oxalate [21].

Patients who have undergone bariatric surgery showed characteristic 24 hour urine parameters including low urine volume, low urinary pH, hypocitraturia, hyperoxaluria, and hyperuricosuria. Nevertheless, the pathophysiology of bariatric surgery-induced hyperoxaluria remains unclear. Potential causes include alteration in intestinal flora (i.e. *Oxalobacter formigenes*), fat malabsorption, or a reduced amount of oxalate secretion [22, 23]. Prevention of stones with dietary limitation of oxalate and sodium and a high intake of fluids is critical, and calcium supplementation with calcium citrate is typically required. Potassium citrate is valuable for treating common metabolic imbalances as it raises urinary pH, enhances the activity of stone inhibitors, reduces the supersaturation of calcium oxalate, and corrects hypokalemia. Both pyridoxine and probiotics have been shown in small studies to reduce hyperoxaluria [24, 25], but further study is necessary to clarify their effects on stone morbidity in the bariatric surgery population.

## Diet and medical therapy

### Dietary modifications and weight loss

Dietary modifications can reduce urinary excretion of stone constituents or increase urinary inhibitors. Dietary changes alone may be sufficient in terms of preventing stone recurrence without the need for drug therapy in low-risk stone formers; however, dietary modifications should always accompany drug therapy in patients at high risk of recurrence. Acidic urine and increased concentrations of sodium, calcium, oxalate, and uric acid may aise the risk of stone disease due to excessive intake of salt, protein, calcium, and a oxalate-rich diet in obese patients. Weight loss and dietary modifications such as increasing fluid and fibre intake, restricted intake of red meat, salt, and oxalate, and mild calcium intake, may alleviate urinary electrolyte changes in some patients [26].

Ekuro et al. found that appropriate dietary modification and tailored medical treatment successfully lowered the recurrence rate of stone disease in obese patients [27]. In general, patients are recommended consuming enough fluid to maintain a urine output of at least 2 L daily. Most beverages can be drunk to increase fluid intake and help prevent stone formation.

### Potassium citrate and urine pH modifications

Potassium citrate acts by providing an alkali load and probably reducing urinary calcium. It increases urinary pH and citrate, thereby increasing urinary inhibitory activity. Potassium citrate can be used in hypocitraturic patients or normocalciuric calcium stone formers regardless of other associated abnormalities. In a randomized trial, potassium citrate was shown to reduce stone recurrence rates by 75% among hypocitraturic stone formers [28]. In patients with gouty diathesis, potassium citrate raises urinary pH and reduces uric-acid-induced calcium oxalate stone formation. It has been shown to be effective in reducing stone recurrence rates for patients with hyperuricosuric calcium oxalate nephrolithiasis and lack of tolerance for allopurinol [29]. Increasing the urine pH above 5.5, preferably between 6.5 and 7.0, plays a key role in the management of gouty diathesis [30]. Potassium citrate should be given at a dose sufficient to maintain urine pH at approximately 6.5. Alkalinizing the urine to a pH higher than 7.0 should be avoided due to increasing risk of calcium phosphate stone formation.

Potassium citrate is prescribed at a starting dose of 10 mEq three times daily, or 20 mEq twice daily. It is prescribed along with a thiazide diuretic or indapamide to reduce the risk of thiazide-induced hypokalemia and hypocitraturia in patients with hypercalciuria. For patients with enteric hyperoxaluria, potassium citrate therapy can raise urine pH and citrate, but the dosages of potassium citrate (up to 120 mEq daily) may be increased higher than used for idiopathic calcium nephrolithiasis.

### Allopurinol

Decreasing the production of uric acid and altering the urinary milieu for the remaining uric acid to be in a dissolved state are two pharmacologic approaches to the management of hyperuricosuric calcium oxalate nephrolithiasis. Allopurinol (300 mg/day) may be used if patients are unable or unwilling to comply with dietary protein restriction. Diluting urine to maintain uric acid at a low concentration and the use of an alkalinizing agent such as potassium citrate (30–60 mEq/day) may promote dissolution of uric acid.

## Interventional therapies

Clinical guidelines of the American Urological Association (AUA) for urolithiasis indicate that spontaneous stone passage is seen in 10–53% for 6–10 mm stones [31]. This shows that patients with a stone size larger than 5 mm may encounter some stone-related complications such as renal colic, urinary obstruction and infection in their lifetime and may require interventional therapies. On the other hand, obesity poses a number of problems in the management of stone disease from diagnosis and imaging through to anesthesia and surgery. Beyond these pitfalls, treatment success of interventional therapy is negatively influenced by obesity as well. Some technical modifications have been outlined by several authors to increase success rates. In this section we emphasize the basic features of these therapies in obese patients.

## Extracorporeal shock-wave lithotripsy

Extracorporeal shock-wave lithotripsy (SWL) has been widely used as the primary treatment modality for most renal and ureteral calculi [32]. Uncorrected coagulopathy, pregnancy, severe skeletal deformity, and morbid obesity are accepted contraindications of this modality. Advantages of SWL for renal and ureteral stones are the avoidance of anesthesia-related complications and the ability to perform the procedure many times without increasing morbidity. On the other hand, exceeding the table's weight limit (135 kg for Dornier HM3) and the short focal length (12–14 cm) of lithotripters restricts the optimal SWL treatment in obese patients [33]. Treatment success for renal stones ≤20 mm was found to be above 90% and was 92.6–97.5% for ureteral stones ≤10 mm in the overall population [32]. However, Delakas et al. suggested that the probability of SWL failure was increased 1.9-fold with a BMI of more than 30 kg/m$^2$ [34]. Munoz et al. found that the success rate of SWL for renal and ureteral stones was 72% in obese patients [35]. Additionally, Ackerman et al. stated that BMI was an independent predictive factor of SWL failure and BMI ≤28 kg/m$^2$ had better treatment results [36]. Recent studies emphasized the importance of skin-to-stone distance (SSD) upon stone clearance measured by the mean of three distances from the renal stone to the skin at 0, 45, and 90° using radiographic calipers or a computational measuring device [25, 37]. Many studies have shown that SWL outcomes worsen when SSD exceeds 10 cm [25, 38–40]. Pareek et al suggested that SSD greater than 10 cm more strongly predicted SWL failure than BMI [41]. Reducing focal length by using an abdominal strap, selecting a lithotripter with a long focal length, and high-energy settings may improve the success rate of SWL [42]. Additionally, Mezentsev states that SWL with the "blast-path" technique in morbidly obese patients enables better treatment success (87%) even if the stone is located a few centimeters from the center of focal area [43]. Treatment of lower calyceal stones is still challenging, as in non-obese patients.

Recently, excessive visceral fat, as measured on non-contrast computed tomography, has been shown to be a useful prognostic tool for SWL outcomes. Juan et al. emphasized that increasing abdominal circumference, visceral fat, subcutaneous fat, and perirenal and pararenal fat are strongly related to decreasing stone-free rates after SWL [44]. Zhou et al. demonstrated that increasing visceral fat was an independent predictor of uric acid stones [45]. Therefore, urinary alkalization should be tailored in obese patients with radiolucent stones and low urinary pH.

Tips and tricks for SWL in obesity are outlined in Box 71.1.

**Box 71.1 Tips and tricks for shock-wave lithotripsy in obese patients.**

Use an abdominal strap to reduce focal length.
Use a long-focal-length lithotripter or high-energy setting.
Use the "blast-path" technique when the stone located a few centimeters from the center of the focal area.

## Ureterorenoscopic treatment

Owing to recent technological advances, retrograde endoscopic lithotripsy for renal and ureteral stones with flexible and semirigid ureterorenoscopy (URS) has become a feasible treatment option. According to the European Association of Urology (EAU)/AUA Guideline Panel on ureteral stones, URS has superior stone-free rates for proximal ureteral stones larger than 1 cm and in all mid-ureteral and distal stones when compared with SWL [46]. Additionally, URS can be safely performed in special circumstances such as pregnancy, ectopic, pelvic, or transplant kidneys, pediatric patients, and patients on anticoagulation medication. Despite SWL being accepted as the first-line treatment modality for renal stones (smaller than 2 cm), it may be precluded by weight limitations of the treatment table and difficulties in focusing on the stone due to impaired radiologic imaging (fluoroscopy or ultrasound) and short focal length [47].

Flexible URS is indicated in renal stones less than 15 mm that do not respond to SWL [48]. Dash et al. stated in a stone-matched comparison (obese vs. non-obese) that URS treatment for renal calculi was effective in obese patients as well as non-obese counterparts without increasing morbidity [49]. Natalin et al. evaluated their URS treatment outcomes of renal and ureteral stones according to BMI, stone size, and location from data of 107 patients [50]. Overall stone-free rates were 91, 97, and 94% in normal, overweight, and morbidly obese patients, respectively. They found no significant difference in terms of stone location (renal/proximal, middle, and distal ureteral stone) and size (cut-off dimension was 1 cm) in all groups. They emphasized that URS treatment is an acceptable modality for all ureteral calculi with a high success rate in obesity and may be preferable to SWL for obese patients [50]. In a multicenter trial, Chew et al. compared URS in patients with normal

BMI values with those considered overweight or obese [51]. No significant difference was found in stone-free rates. Recently, Ishii et al. conducted a systematic review which analyzed the data of 15 studies and 835 patients with a mean BMI of 40.5 kg/m$^2$ [52]. According to cumulative analysis, the initial and final stone-free rates were 76.9 and 82.5%, respectively, with an overall complication rate of 9.3%. The overall stone size was 14.2 mm (range 3–72 mm) with almost a third of the stones in the lower pole. The complication rate for morbidly obese patients (17.6%) was twice that of the obese patients (8.4%), although they were all graded as Clavien I or II. Consequently, they concluded that URS and stone fragmentation are safe and efficient treatment methods in obese patients with a good stone-free rate and a relatively low complication rate.

Generally, additional technical modifications are not recommended when performing URS in obese patients. To prevent further interventions, recent developments in URS treatment such as digital flexible URS, ureteral access sheath, holmium laser lithotripsy, and nitinol stone baskets may be used [53]. Flexible URS may act as a guide for percutaneous renal access in obese patients after failure of a prior attempt. Khan et al. defined a technique in which flexible URS advances to the intended calyx with the patient in a prone split-leg position and exact percutaneous calyceal puncture is performed under direct vision [54].

## Percutaneous nephrolithotomy

Percutaneous nephrolithotomy (PCNL) is recommended for kidney stones larger than 2 cm and staghorn calculi [55]. PCNL is also indicated in cases of SWL failure, stones with concurrent ureteropelvic junction obstruction, stones within calyceal diverticula, and anatomic abnormalities (i.e. horseshoe kidney). The absolute contraindications are active urinary infection and uncontrolled coagulopathy. Studies suggested that the success and complication rates of PCNL in obese patients are comparable with the normal-weight population [56–58].

Pearle et al. found that the stone-free rates of staghorn and non-staghorn stones in obese patients were 84.2 and 90.2%, respectively [56]. Of the patients, 14% had minor or major complications, 8.8% needed blood transfusion, and hospital stay was 4.9 days. They also stated that technical modifications and appropriate instrumentation are necessary for improving stone-free rates in this group of patients. Similarly, El-Assmy et al. reported 4 year PCNL experiences in 1121 patients from their retrospective clinical data [58]. They found the stone-free rate of obese patients were 84.7%. Hematuria requiring blood transfusion (3.2%) and septicemia (2.1%) were the most common major complications in the obese and morbidly obese groups. The complication rate and length of hospital stay were also similar to those in the non-obese group. In conclusion, they stated that PCNL is a feasible and effective procedure in obese and morbidly obese patients as well as in their non-obese counterparts [58]. Kuntz et al. found no difference in stone-free rates, complications, auxiliary procedure rates, or length of stay among patients stratified by BMI, and proved that “tubeless” PCNL could be performed safely in these individuals [59].

The Clinical Research Office of Endourological Society (CROES) PCNL multicenter global study included 3709 PCNL patients. Fuller et al. found equivalent stone-free rates for normal, overweight, and obese cohorts (approximately 80%), but significantly lower stone-free rates for the morbidly obese group (65.6%) [60]. They also concluded the complication rates were not associated with BMI, while patients with high BMI were likely to have comorbid conditions.

Traditionally, PCNL has been performed in the prone position. This position facilitates posterior access to the collecting system through Brödel’s avascular renal plane without causing significant parenchymal bleeding, peritoneal perforation, or visceral injuries. However, prone PCNL often causes respiratory system problems due to restriction of the patient’s chest movement and surgery may not be sustained in this position. The anesthesiologist and the surgeon generally struggle in this situation in morbid obese patients due to compromised cardiopulmonary status and body weight.

Increased knowledge of renal anatomy and clinical experience on PCNL has encouraged urologists to modify prone positioning in an effort to improve results and overcome these limitations. Recent literature has focused on alternatives in patient positioning, widening patient selection, or new techniques (i.e. tubeless PCNL). Gofrit et al. defined lateral decubitus positioning for PCNL in morbidly obese or kyphotic patients [61]. Valdivia et al. first described PCNL in supine position for a patient at high anesthesiologic risk [62]. After pioneering this technique, several authors have reported their experiences [63–68]. The supine position has several advantages such as decreasing anesthetic requirement, preventing respiratory system-related complications, and allowing a simultaneous retrograde ureteroscopic approach. In addition, urologists are more comfortable adopting a sitting position during stone management. Difficulties in filling of the collecting system against gravity, small surgical field for nephroscopic maneuvers, and the challenges of advancing the needle into the upper calyx are some limitations of supine PCNL.

A randomized prospective study was conducted to compare the outcomes of PCNL in supine and prone position. They found the treatment success of supine and prone PCNL were 77 and 80%, respectively [69]. In a comprehensive review, de la Rosette et al. emphasized that prone PCNL seems to be more feasible, with decreased operative times, similar bleeding rates, and slightly better stone-free rates than supine PCNL [70]. In contrast, Manohar et al. reported that the stone-free rate of supine PCNL in high-risk and morbidly obese patients was 95% [65]. Although the supine position seems to have some advantages for obese and morbidly obese patients and patients with staghorn calculi, the prone position has better outcomes over the supine position.

Percutaneous access into the pelvicalyceal system can be more difficult in obese patients. The authors defined some modifications to cope with these difficulties. Grasso et al. reported a technique of passing a flexible ureteroscope to capture the percutaneously inserted guidewire and establish through-and-through access at the beginning of the procedure [71]. Additionally, morbidly obese patients generally have excessive subcutaneous and fatty tissues with which standard PCNL instruments are too short to reach the stone. Segura described a technique for incising the skin and fat. Incision extends down to the muscular fascia and gains the extra length required to reach the stone [72]. Another option is to dilate the tract and place a nephrostomy tube for 1 week to let the tract mature. In some cases, maturation of the tract allows the kidney to fall back posteriorly closer to the skin, allowing the use of standard nephroscopic instrumentation. Flexible nephroscopy also can be performed through the mature tract, reducing the necessity of rigid nephroscopy [47, 56]. Giblin et al. reported the use of a long Amplatz sheath in combination with a 30 Fr gynecological laparoscope with a working length of 27 cm to treat stones in morbidly obese patients [73]. In addition, favoring the shortest tract for percutaneous access and using a longer device such as an Amplatz sheath longer than 17 cm, a longer nephroscope may facilitate the procedure. Moreover, using a ureteroscope through a percutaneous site may be helpful.

Another technical problem specifically encountered in these patients is migration of the Amplatz sheath beneath the skin or muscle fascia (Figure 71.1). Bugeja et al. described a simple technique, making use of a modified 10 mL syringe barrel to facilitate retrieval of a migrated access sheath in obese patients during PCNL [74]. We recommend using two sutures on the Amplatz sheath to prevent it getting stuck under the skin (Figure 71.2). In this situation, these sutures allow pulling it back out of skin manually or using the open jaws of grasping forceps (Figure 71.3). If all those techniques fail, a Foley catheter can be inserted into the sheath (Figure 71.4). Then, pull out the sheath out after inflating the balloon. Surgeons should pay attention to type of nephrostomy tube used in obese patients. Tube displacement tends to occur more often in morbidly obese patients, so balloon-type catheters or re-entry Malecot catheters may be preferable [75]. Tips and tricks for PCNL in obesity were shown in Box 71.2. A video of standard prone PCNL in an obese patient is available (see Video 71.1).

## Conclusion

Epidemiological studies state that obesity increases the risk of urolithiasis. Several pathophysiological mechanisms cause abnormalities in urine composition in obese patients. These include carbohydrate-induced calciuria, increased protein intake, effects of insulin resistance on renal ammonia metabolism and urine pH, the increased prevalence of gout and hyperuricosuria, or some other unidentified abnormality in renal electrolyte transport.

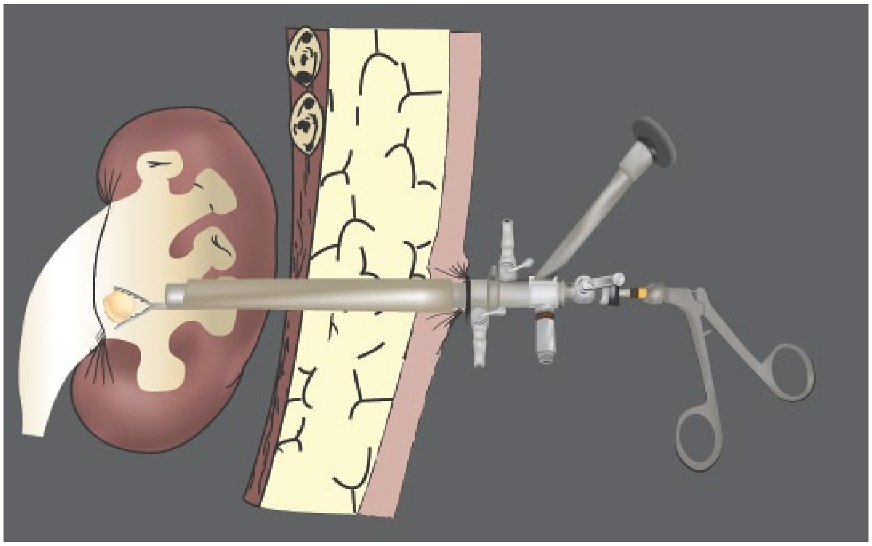

**Figure 71.1** Migration of the Amplatz sheath beneath the skin during PCNL in obese patients.

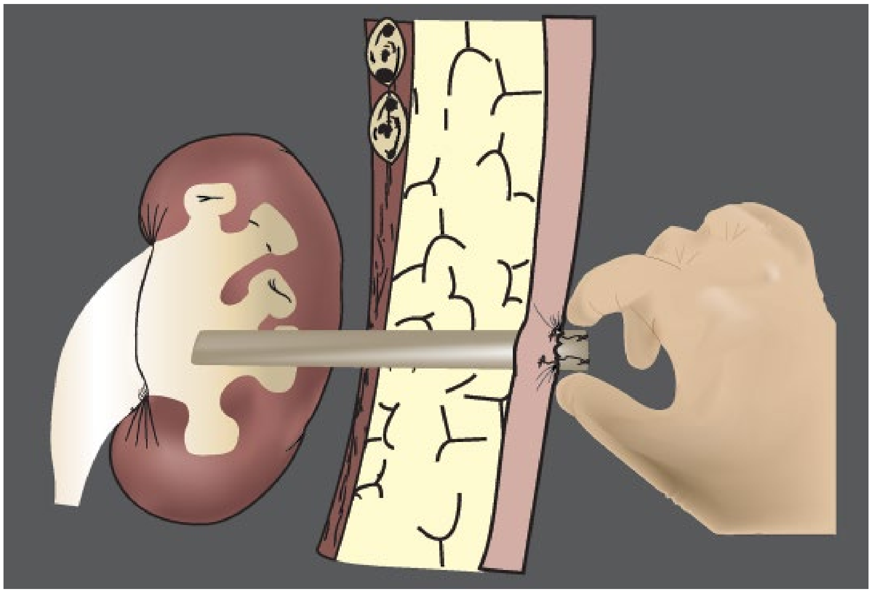

**Figure 71.2** Using two sutures on the Amplatz sheath to prevent it getting stuck under the skin, allowing the surgeon to pull it back out of the skin manually.

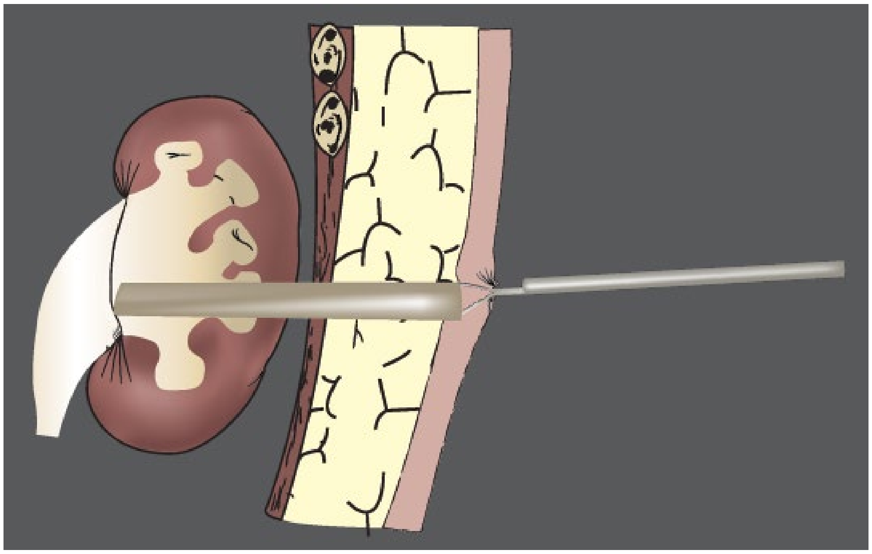

**Figure 71.3** Using the open jaws of grasping forceps to retrieve an Amplatz sheath.

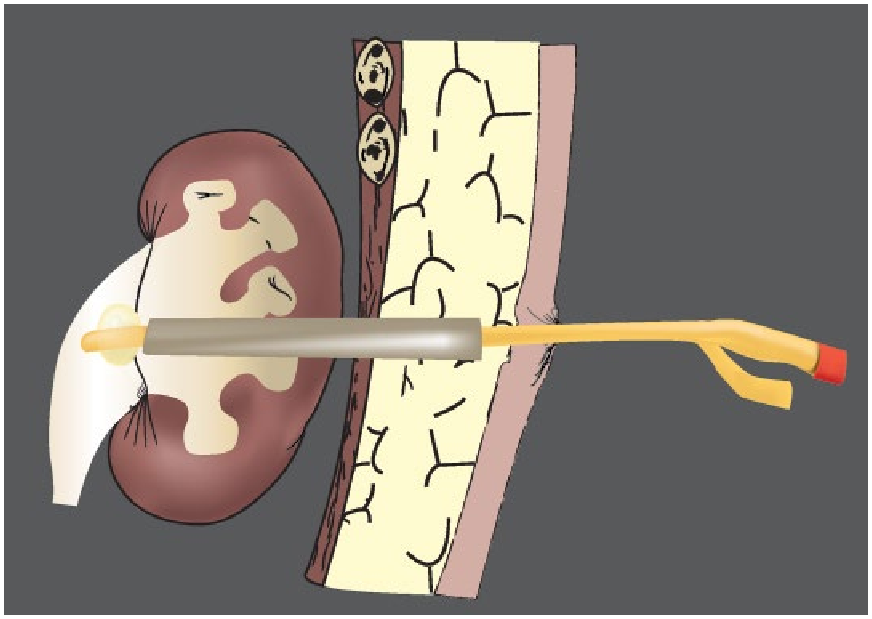

**Figure 71.4** Inserting a Foley catheter into the sheath and trying to pull out it after inflating the balloon.

**Box 71.2 Tips and tricks for percutaneous nephrolithotomy in obese patients.**

Dilate the tract and place a nephrostomy tube for 1 week to let the tract mature.
Use long Amplatz sheaths and nephroscopes.
Favor the shortest possible tract.
Stitch two sutures on the Amplatz sheath.
Balloon-type catheters or re-entry Malecot catheters may be preferable as a nephrostomy tube.
Use supine position in selected patients (to overcome ventilation problems).

Dietary modifications have an important role because metabolic abnormalities are more common in obese stone formers. Medical treatment has been shown to reduce the risk of stone formation. Weight-loss diets and bariatric surgery may cause increased risk of stone disease due to low pH and hyperuricosuria.

Obesity poses a number of problems in the management of stone disease from diagnosis and imaging through to anesthesia and surgery. Comorbidity will be increased and anaesthesia will need special expertise in this group of patients. Extracorporeal SWL has some limitations in morbidly obese patients in terms of exceeding the operating table weight limit and focusing the stone. Several techniques have been described to overcome this limitation in some patients. Flexible URS technology is gaining worldwide acceptance because of high stone clearance rates. PCNL can be modified in obese patients allowing similar outcomes and morbidity to the non-obese patient. To manage obese patients with urolithiasis safely and effectively, the urologist should have enough knowledge about and experience of potential diagnostic and treatment problems, and be aware of the relevant modifications of the standard techniques.

### Introduction

The economic impact of nephrolithiasis is as important as ever as disease prevalence continues to rise. The most recent National Health and Nutrition Examination Survey (NHANES; 2007–2010) data indicate that kidney stones will affect nearly one in 11 (8.8%) people in the United States, up from 5.2% in 1988–1994 and 3.2% in 1976–1980 [1, 2]. In 2000 it was estimated that spending on treatment of urolithiasis eclipsed US$2 billion, nearly double that spent just 6 years previously ($1.37 billion) [3]. Other estimates suggest an additional cost of urolithiasis treatment of $1.24 billion/year by 2030 if the prevalence of diabetes and obesity continue to rise along with expected population growth [4]. Additionally, as stone disease is most prevalent among working-age individuals, lost work hours contribute a substantial indirect cost [5]. Taken together, these statistics highlight the considerable economic impact of stone disease, for both the individual and society as a whole.

### Assessing and analyzing cost

The reality of limitations on available resources increasingly requires that physicians understand the influence of economics, or, more simply, cost, in terms of how medical care is delivered. Healthcare economics influences the availability of operating room equipment/instruments and disposables, patient access to medication, and in the setting of such limitations physicians must consider not only efficacy but also cost when selecting treatments.

The definition of cost often varies with the perspective of the group that bares the cost, making it anything but consistent to measure. Patient cost refers to out-of-pocket expenses for a given treatment. This can vary significantly by insurance status, which in countries like the United States can be related to employment, with related deductible or co-pays required. Societal cost is another term, one that can have a drastically different meaning depending on the healthcare system. For instance, there is a direct impact on the nation's budget for countries like Canada or the United Kingdom with national healthcare systems, whereas in the United States only the healthcare needs of selected groups are covered by government-funded programs such as Medicaid or Medicare, which ties the healthcare economics to overall budgetary concerns. This is not to mention cost of capital and disposable equipment as well as the level of subsidization, which will undoubtedly vary by country [6]. Common to all countries are indirect economic costs, which are sometimes even harder to quantify. Examples of indirect costs include lost wages secondary to illness and/or treatment.

It is typically much easier to define hospital costs and expenditures; thus, much of the research on healthcare costs are from the hospital's perspective. Despite the fact that hospital costs will undoubtedly vary between centers and countries, many shared concepts exist in this space: the purchase and maintenance costs of capital equipment such as lithotripters, the cost of labor for both physicians and other healthcare workers, medication costs, and services and supplies used during hospitalization.

Not to be overlooked, any discussion involving the financial impact of treatment requires distinguishing the terms "charge" and "cost." Charge includes both the direct cost of an item/service and the indirect cost associated with its supply. Cost most commonly refers to the direct cost to the hospital to provide a service or purchase an item. One big difference is that charge involves a defined profit margin whereas cost does not. The cost-to-charge ratio usually varies between surgical procedures.

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.
© 2019 John Wiley & Sons Ltd. Published 2019 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/smith/textbookofendourology

For example, a hospital may choose to collect a larger profit margin from one particular service than another despite a lower actual cost. Overall charge appears on the bill, although its components are often difficult to identify. The most accessible data to researchers are often the hospital billing statement; thus charges are unfortunately frequently used when performing cost analyses. The arbitrary nature of charge data means that it may not consistently relate to actual cost; however, cost data, as previously mentioned, are not without their own inherent flaws.

Lastly, medical decision-making should include outcomes other than cost considerations. Other variables such as stone parameters, patient factors and preferences, available equipment, and surgeon preference may, in many situations, outweigh cost considerations in selecting the best stone treatment option for a given patient.

The remainder of this chapter will discuss cost with respect to diagnosis and treatment of ureteral stones, renal stones, and medical management to prevent stone recurrence.

## Ureteral stones

Treatment of ureteral stones requires consideration of the following factors: diagnosis, determining the need for surgical intervention, and, if surgery is necessary, choosing the optimal surgical treatment. Each decision along the course of treatment has associated cost considerations that impact the overall cost for each treatment strategy.

### Diagnosis

For many years now computed tomography (CT) has been the gold-standard imaging modality for diagnosing ureteral stones. CT scanning has a sensitivity of 98% and a specificity of 95–100% for diagnosing calculi [7, 8] and can also more frequently diagnose the etiology of pain when calculi are not present [7]. In recent years ultrasound (US) has challenged the widespread use of CT due to concerns regarding long-term effects from exposure to ionizing radiation (with CT), CT having a high rate of incidental findings that have the potential to create unnecessary follow-up evaluation, higher cost of CT compared to US, and ease of access to US with more emergency department (ED) physicians obtaining training and certification in point-of-care US. Smith-Bindman et al. performed a multicenter randomized control trial (RCT) to assess the effects of US and CT for suspected nephrolithiasis [9]. Patients who presented to the ED during the daytime (2759) suspected of having nephrolithiasis were randomized to US performed by the ED physician, US performed by a radiologist, or CT. The primary outcome was 30 day incidence of high-risk diagnoses with complications that could be related to missed or delayed diagnosis. The results demonstrated that incidence of high-risk diagnoses with complications did not vary significantly between groups, with the overall rate being low at 0.4%. There were also no significant differences in return ED visits or hospitalizations between the groups. Patients in the US groups were more likely than those in the CT group to undergo additional testing during the initial ED visit (40.7% for ED US, 27% for radiology US, and 5.1% for CT); however, mean total costs for the ED visit was lower by $25 for patients assigned to US than to those assigned to CT ($P < 0.001$). These results suggest that US can be safely used as an initial imaging modality when nephrolithiasis is suspected and leads to a lower overall ED visit cost. This study was not without limitations, especially patient selection prior to randomization. It is also does not address the impact of imaging on subsequent stone treatment or the overall cost of care beyond the ED visit. Thus it is always important to consider clinical context when selecting an imaging study for stones.

### Observation with medical expulsive therapy

In the absence of obstruction and under the correct clinical circumstances, it is reasonable to observe a patient for spontaneous stone passage. Lotan et al. created a decision-tree model in 2002 that showed that if observation did not fail, and no additional financial costs emerged such as ED visits or future surgery, observation was the least costly pathway compared to lithotripsy or ureteroscopy (URS) [10]. However, it is not always easy to predict which patients will pass their stone spontaneously, with studies showing anywhere from 13 to 75% failure of spontaneous passage based on size and location and 17–33% ultimately requiring intervention [11, 12].

The likelihood of spontaneous passage of ureteral calculi depends on ureteral anatomy, stone size, and stone location [11, 13]. Spontaneous passage rates increase the more distal the location of the stone at diagnosis and vary inversely with stone size [13]. Numerous pharmacologic agents have been shown to increase the likelihood of spontaneous passage, thus eliminating the need for surgery or further intervention. These drugs constitute so-called medical expulsive therapy (MET) [14]. The use of MET became widespread based on small RCTs and meta-analyses that demonstrated medication use increased stone passage rates at relatively low cost. However, this conclusion was recently called into question. A large, multicenter placebo-controlled RCT was performed in the United Kingdom in which 1167 patients with ureteral stones ≤10 mm were randomized 1:1:1 to tamsulosin 0.4 mg (alpha-blocker), nifedipine 30 mg (calcium channel blocker), or placebo to determine the proportion of patients who did not require further intervention for stone clearance within 4 weeks of randomization [15]. The study demonstrated that neither tamsulosin nor nifedipine was effective at decreasing the need for further treatment for patients with expectantly managed ureteral stones at 4 weeks, even after adjusting for factors such as stone size and location (Table 72.1). After further extensive sensitivity analyses of the same data it was demonstrated that MET was not cost-effective with either drug, owing to the fact that there was no difference in quality-adjusted life years gained or in cost between the trial groups [16]. Table 72.2 displays these cost data.

Since the primary outcome of the UK multicenter RCT was no need for additional intervention at 4 weeks as opposed to radiographic evidence of stone passage, MET continues to be used to aid passage of distal ureteral stones. Outside of this indication its use has largely fallen out of favor.

## Immediate decompression

If ureteral obstruction is present and infection is suspected/present, immediate decompression of the collecting system is paramount. The two options for decompression include internal ureteral stent placement or percutaneous nephrostomy. Two RCTs have addressed the choice of optimal modality to treat infection in the setting of ureteral obstruction. Pearle et al. randomized 42 patients with suspected infection and obstruction to either ureteral stent or percutaneous nephrostomy, and compared cost and time to clinical improvement [17]. The two modalities were found to be equally effective with respect to the time to normalization of white blood count and/or patient temperature; however, percutaneous nephrostomy was less costly ($1137 vs. $2401, respectively) due to stent placement being performed under general anesthesia. Mokhmalji et al. randomized 40 patients with hydronephrosis due to ureteral calculi both with and without signs of infection to either receive stenting or nephrostomy [18]. The authors concluded that percutaneous nephrostomy was the superior method of decompression due to shorter antibiotic treatment duration (0 vs. 64% requiring antibiotics for longer than 5 days, respectively), reduced time to definitive stone treatment (25 vs. 50% with need for diversion at 2 weeks, respectively), and need for less fluoroscopy (10 vs. 40% with >2 min, respectively). Cost was not evaluated in the later study.

**Table 72.1** Primary outcome results, no need for intervention at 4 weeks.

| | **Odds ratio (95% CI); *P* value** | **Risk difference (95% CI)** |
|---|---|---|
| MET vs. placebo | | |
| Unadjusted | 1.04 (0.77–1.43); 0.76 | 0.8% (−4.1 to 5.7) |
| Adjusted | 1.06 (0.70–1.60); 0.78 | 0.9% (−5.1 to 6.8) |
| Tamsulosin vs. nifedipine | | |
| Unadjusted | 1.07 (0.74–1.53); 0.73 | 1.0% (−4.6 to 6.6) |
| Adjusted | 1.06 (0.73–1.53); 0.77 | 0.8% (−4.5 to 6.1) |
| Tamsulosin vs. placebo | | |

In general, percutaneous nephrostomy is highly successful in the setting of hydronephrosis due to the large, dilated collecting system. Failed stent placement due to complete ureteral obstruction, which has been reported to occur in up to 20% of cases, is a definite cost concern in favor of nephrostomy as stent failures will incur the additional cost of salvage [18]; however, currently there are no data comparing costs that take into account failed stent placement.

Presuming equal efficacy for decompression in the acute setting of infection and obstruction, the choice of stent placement versus nephrostomy is commonly based on factors other than cost, such as availability of the interventional radiologist versus the operating room, stone size and/or location, physician, and patient preference.

## Surgical intervention

Surgical intervention must be considered for stones that are unlikely to or have failed to pass based on aforementioned patient and stone characteristics. The mainstays of treatment for ureteral stones are URS and shock-wave lithotripsy (SWL). The 2016 American Urological Association (AUA)/Endourological Society Surgical Management of Stones Guideline [19] states that URS should be offered as first-line therapy for patients with mid or distal ureteral stones who require intervention (those who are not candidates for or who fail MET), as URS is associated with significantly higher stone-free rates in a single procedure than SWL in this setting.

**Table 72.2** Summary of costs.

| | Intervention {*n*, mean [median] (SD)} | | |
|---|---|---|---|
| **Resource** | **Tamsulosin** | **Nifedipine** | **Placebo** |
| Intervention | 383, £4.96 | 383, £6.95 | 384, £0 |
| Analgesics and antibiotics | 383, £4 [£5] (2) | 383, £4 [£5] (2) | 383, £4 [£5] (2) |
| Diagnostic tests[a] | 383, £96 [£120] (40) | 383, £94 [£120] (36) | 383, £98 [£120] (41) |
| Doctor visits | 329, £9 [£0] (30) | 331, £8 [£0] (30) | 325, £6 [£0] (24) |
| Nurse visits | 329, £0.57 [£0] (5) | 330, £0.28 [£0] (2) | 325, £1.14 [£0] (14) |
| Outpatient visits[b] | 377, £73 [£101] (74) | 378, £64 [£101] (67) | 379, £67 [£101] (70) |
| All interventions[c] | 378, £250 [£0] (581) | 379, £267 [£0] (608) | 379, £291 [£0] (632) |
| Excess admission days[d] | 375, £44 [£0] (169) | 377, £62 [£0] (279) | 375, £65 [£0] (298) |
| Total costs[e] | 325, £326 [£228] (494) | 329, £335 [£227] (557) | 323, £367 [£223] (619) |

[a] Includes tests conducted at baseline, 4 weeks and participant-reported tests.
[b] Includes 4 week clinic attendance and participant-reported outpatient visits.
[c] Cost of all interventions as some participants had more than one intervention in a visit.

Studies comparing URS versus SWL for distal ureteral stones reported the overall success rate for distal ureteral stones to be approximately 92% for URS (2539/2751) compared to 65% for SWL (2260/3488; $P < 0.001$) [20]. SWL is an acceptable alternative for patients who decline URS as it has lesser morbidity and a lower complication rate. The disparity in stone-free rate was greater for mid and distal ureteral stones than proximal ureteral stones, hence the delineation in the guideline.

Costs for URS and SWL differ in great part due to differences in complication rates, stone-free rates, and equipment costs between the two procedures. Furthermore, factors other than cost influence surgical treatment choice, including patient preference, surgeon skill, stone characteristics, and equipment availability. While numerous studies have been performed to assess cost of URS versus SWL, they are plagued by overuse of charge data rather than cost data, lack of uniform inclusion of costs of preoperative evaluation, costs of disposables or other equipment, cost of lost work productivity, and charges associated with complications.

Decision analysis models have been created to eliminate differences across institutions. These models provide theoretical tools for use in comparing the cost of different treatments. Inherent to these models are a series of assumptions about treatment choices, cost, and outcomes. One such model, a decision-tree analysis, was used by Lotan et al. to compare observation, URS, and SWL for the treatment of ureteral stones. The authors went a step further, stratifying patients according to stone location (distal, middle, or proximal ureter). For each location, observation was the least costly strategy, provided the cost of additional treatment and missed work or evaluation (such as ED visits) did not exceed $456 [10]. Comparing the two surgical treatments, SWL was more costly than URS for all ureteral locations by $1750, $1670, or $1440 for patients with distal, middle, and proximal ureteral stones, respectively, principally due to the high cost of purchase and maintenance of a lithotripter. Two-way sensitivity analyses were performed for SWL and URS at different costs and success rates to determine overall cost of treatment according to the model. This analysis enabled the construction of a universally generalizable table, which allows for the identification of the least costly treatment option within a large range of costs ($2000–5000) and success rates (50–95%).

URS continues to be more cost-effective than SWL [21] in managing ureteral stones given high costs of lithotripters compared to ureteroscopes, and the lack of greater efficacy of SWL. Ureteroscope repair costs are balanced out by high annual maintenance costs of the lithotripter.

## Ureteroscope maintenance and repair

Despite evidence in the literature supporting the cost-effectiveness of URS over SWL, maintenance and repair of ureteroscopes can threaten the ability to maintain a URS program. For this reason, numerous studies have assessed the burden of ureteroscope repair on revenue, specifically focusing on frequency of repairs and how accessory tools can affect scope durability.

Tosoian et al. identified maintenance and repair of ureteroscopes as a possible threat to profits and sustainability of the URS program [22]. During the fiscal year of 2013, 190 ureteroscope cases were reviewed during which 20 ureteroscope repairs were required, totaling $115 000 in indirect variable costs. Despite the significant cost of ureteroscope repair, URS cases generated an average profit of $594. The cost of ureteroscope repair per case averaged $605. Furthermore, the study found that for a net loss in revenue, ureteroscope repair would have to exceed $1199 per case.

Carey et al. assessed the rate at which new and previously used ureteroscopes were damaged and required repair [23]. In this study, new ureteroscopes, which at the time included the DUR-8, DUR-8 Elite, and Flex-X 7.5, were used 40–48 times before repair was required. Ureteroscopes that were previously repaired, which included the DUR-8, AUR-7, AUR-9, and 11274AA, required repair after an average of 11.1 cases. The study concluded that disposable costs for refurbished ureteroscopes requiring repair after an average of 11 cases were not as cost-effective when compared to purchasing a new ureteroscope, which can achieve almost triple the number of cases before repair.

In a later review of 501 URS cases at a tertiary care center, an average of 6.9 cases were performed before additional major repairs were needed in already refurbished ureteroscopes. In this study ureteroscopes were sent to an outsourced vendor as opposed to being sent to the original manufacturer [24]. This may account for the reduction in average number of cases before additional major repairs are needed. Nevertheless, costs for refurbished ureteroscopes in this study totaled $129 635.65, which is of concern considering the likelihood of these ureteroscopes frequently needing additional repairs.

Clearly outlined in the studies previously discussed, repair of ureteroscopes is inevitable. However, other research has shown that the durability of ureteroscopes can be maximized with the use of certain accessory instruments during URS and with proper precautions taken during maintenance.

Pietrow and colleagues evaluated the effects that use of ureteral access sheaths, 200 μm holmium laser fibers, and nitinol baskets/graspers have on frequency of ureteroscope repair [25]. A total of 109 URS procedures with four new flexible ureteroscopes were reviewed, in which an average of 27.5 procedures were performed before repair was necessary. Literature prior to the study showed that the average range of cases before necessary repair was 6–15 [26], concluding that the use of specific ureteroscope accessories can prolong durability and decrease necessary repair.

In regards to ureteroscope maintenance, Semins et al. proposed that training house staff in handling ureteroscopes during processing is necessary to minimize unnecessary repair [27]. In their study, a 12 month period where trained nursing staff handled, cleaned, and sterilized ureteroscopes was compared to a prior 12 month period where ureteroscopes were sent to central supply for cleaning and sterilization. Trained nursing staff averaged 28.1 cases before repair was needed. More importantly, no ureteroscope damage could be attributed to cleaning, sterilizing, or storage. For ureteroscopes sent to central supply, an average of 10.8 cases were performed before ureteroscopes needed to be sent out for repair. Reasons for repair included a fractured light cord attachment and fractured eyepiece, damage that may have occurred during processing. These common-sense interventions can be instituted to reduce ureteroscope repair costs.

In 2016, Boston Scientific began advertising the LithoVue, a single-use digital flexible ureteroscope that is intended to eliminate the high costs of ureteroscope reprocessing, sterilization, and repair. A recent study by Proietti et al. compared ureteral and calyceal access, maneuverability, and visualization in the single-use scope and conventional fiber-optic and digital flexible ureteroscopes in cadavers [28]. Subjective review by performing surgeons found the LithoVue to be comparable with regard to visibility and manipulation. If the LithoVue gains popularity in the near future, its expanded use in URS programs could yield more information on cost savings compared to conventional reusable ureteroscopes.

## Post-ureteroscopy imaging

Routine imaging in post-URS patients has been controversial. Although most patients with ureteral obstruction will present with symptoms (flank pain, nausea, vomiting) prompting urological imaging to rule out obstructive pathology, there are a few who can be asymptomatic. In a cohort of 241 patients who underwent URS and had a mean follow-up of 5.4 months with imaging, Weizer et al. identified seven patients who required second URS due to silent obstruction [29]. One patient required permanent hemodialysis making an obvious case for the importance of post-URS imaging to prevent organ loss. Bugg et al. reviewed 77 patients who underwent URS for stone disease and had a mean 7 weeks follow-up with imaging. They found that 96% of patients who did not have preoperative obstruction and no complaints of postoperative pain to have no postoperative obstruction or residual stone disease [30]. A retrospective review of 289 patients who underwent URS with renal US at 1 month follow-up identified 14 patients with asymptomatic hydronephrosis, 21% of whom required further surgery [31].

A recent survey study revealed that only 48% of urologists obtain post-URS imaging. Reasons for not obtaining imaging included cost, radiation exposure, and diagnostic inaccuracy of US [32]. When comparing cost of imaging for all post-URS patients with selective imaging in symptomatic patients, analysis by Sutherland et al. suggests that routine postoperative imaging in all patients imparts a $130 incrementally higher cost per patient compared to selective imaging ($5326 vs. $5196, respectively) [33]. Furthermore, it was projected that medical expenses for patients who do lose a kidney secondary to silent obstruction would still be offset by the cost savings from selective imaging. Assuming a 2% rate of silent obstruction this amounts to $6262 per kidney saved. Table 72.3 shows cost by variable silent obstruction rates and imaging costs [33].

Given the potentially devastating complication of organ loss and greater overall cost of care if this were to transpire, routine post-URS imaging should be considered in all patients.

## Renal stones

In general, the literature regarding cost of treating renal calculi is less robust than that for ureteral calculi. Commonly used treatment modalities for patients with renal calculi are SWL, URS, and percutaneous nephrolithotomy (PCNL).

**Table 72.3** Cost by variable silent obstruction rates and imaging costs.

| | Imaging cost ($) | | Cost difference/ patient ($) | Cost/kidney lost ($)[a] |
|---|---|---|---|---|
| | Routine | Selective | | |
| % Silent obstruction | | | | |
| 0% | 5317 | 5089 | 219 | Not applicable |
| 1% | 5322 | 5149 | 172 | 17 224 |
| 2% | 5326 | 5201 | 125 | 6262 |
| 3% | 5330 | 5252 | 78 | 2608 |
| 4% | 5335 | 5304 | 31 | 781 |
| Imaging cost ($) | | | | |
| $100 | 5162 | 5170 | −8[b] | – |
| $200 | 5264 | 5186 | 78 | – |
| $500 | 5568 | 5234 | 334 | – |
| $800 | 5873 | 5282 | 591 | – |
| $1000 | 6076 | 5314 | 762 | – |

In 2016 the AUA, in conjunction with the Endourological Society, consolidated guidelines for patients with renal stones [34]. The guidelines now stratify patients according to total stone burden and stone location. The recommendation for symptomatic stone(s) in the lower pole ≤10 mm includes SWL or URS, whereas for stone(s) >10 mm SWL should not be offered as first-line therapy. Symptomatic patients with a total non-lower pole renal stone burden ≤20 mm may be offered URS or SWL, as these procedures have acceptable stone-free rates and less morbidity compared to PCNL. Patients with renal stone burden >20 mm should be offered PCNL, and not SWL, as first-line therapy, the rationale being significantly higher stone-free rates for PCNL and the increased need for multiple treatments for SWL in this setting.

### Staghorn stones

PCNL monotherapy is well established as the preferred initial treatment modality for staghorn calculi, due to superior efficiency, efficacy, and cost-effectiveness. One of the first studies to demonstrate cost-effectiveness of PCNL for staghorn calculi was performed by Chandhoke. He developed a "cost-effectiveness index," defined as treatment cost divided by stone-free rate, plus cost of complications multiplied by the complication rate, for different treatments for staghorn calculi. The concept was to demonstrate the average cost of rendering one patient stone free [35]. The model created used complication rates and efficacy from the 1994 AUA Staghorn Calculi Guidelines and charge data from his own institution. He then formulated a decision analysis evaluating PCNL, SWL, and combination therapy (PCNL/SWL). He calculated that PCNL monotherapy was the most cost-effective modality with SWL monotherapy being the least cost-effective. The actual cost-effectiveness index varied by type of secondary treatment used (percutaneous-based vs. URS). Assuming URS as the secondary procedure, cost-effectiveness indices were $36 672 for PCNL monotherapy, $48 095 for combination therapy, and $52 251 for SWL monotherapy.

### Lower pole calyceal stones

New guidelines notwithstanding, optimal management of lower pole renal calyceal calculi continues to be an area of debate. Albala et al., as part of the Lower Pole Stone Study Group, reported the results of a prospective RCT comparing PCNL and SWL for the management of single lower pole stones [36]. They found inferior overall stone-free rates for SWL versus PCNL (37 vs. 95%, respectively), with increasing stone size resulting in more pronounced differences. May and Chandhoke [37] conducted a cost analysis similar to the previously mentioned Chandhoke analysis [36] of staghorn calculi. Despite lower initial success rates, their analysis showed that SWL was more cost-effective than PCNL for treating patients with lower pole stones <2 cm, while PCNL was more cost-effective for stones >2 cm [37].

### Cost factors for PCNL

To better understand the cost component of PCNL, Bagrodia et al. performed a retrospective review of institutional hospital cost data for 179 patients who underwent PCNL [38]. Results of multivariate analysis showed that only stone size was an independent predictor of higher procedural cost. Further analysis by the same authors determined that larger stone burdens tended to increase the need for second-look nephroscopy, which ended up being the main determinant that drove costs higher. Interestingly, factors not predictive of cost were patient age and comorbidities, including obesity.

As PCNL allows for manual removal of all stone material, it has become less acceptable to leave any stone behind. Residual fragments after PCNL, or any stone procedure for that matter, place the patient at risk for future stone events. While the cost of observing versus treating residual fragments after SWL has not been addressed, Raman et al. evaluated the cost-effectiveness of post-PCNL second-look nephroscopy with a decision-tree model [39]. Kaplan–Meier estimates were used to determine the likelihood of a stone-related event. Previously, these authors determined that patients with fragments ≤2 mm had 3 and 5 year survival rates (survival indicating freedom from a stone-related event) of 87 and 65%, respectively, compared to survival rates of 56 and 33%, respectively, for patients with residual fragments >2 mm ($P = 0.04$) [40]. The model demonstrated that for patients with residual fragments ≤4 mm, observation was more cost-effective than second-look flexible nephroscopy, and vice versa for residual fragments >4 mm. Based on these results and the natural history data on residual stones after PCNL, the authors advocate a strategy of second-look nephroscopy for residual fragments >4 mm and observation for ≤2 mm.

### Tubeless PCNL

Tubeless PCNL was first implemented to reduce postoperative pain and shorten convalescence in uncomplicated PCNL procedures. Bellman et al. matched 50 patients by age, gender, and procedure (tubeless vs. standard PCNL), and compared complications, analgesia requirements, length of hospitalization, and cost of treatment between groups [41]. Patients undergoing tubeless PCNL had significantly shorter length of stay (0.6 vs. 4.6 days, $P = 0.0001$) and less morphine sulfate use (11.58 vs. 36.06 mg, $P = 0.001$), both of which contributed to a $2112 cost saving per case (tubeless $1638 vs. standard $3750). Time to return to normal activities was also shorter by nearly 9 days. This result has been replicated in other studies as shown in Table 72.4. The main cost-savings component for tubeless PCNL is shorter hospital stay with associated lesser costs of inpatient care. Since the original description by Bellman et al. tubeless PCNL has been shown to be safe and effective for use in children, simultaneous bilateral procedures, staghorn stones, supracostal access, in obese patients, and in renal units with anatomical anomalies [44]. When a secondary procedure is not needed, tubeless PCNL has a clear cost advantage compared to standard PCNL.

**Table 72.4** Cost data of tubeless versus standard (tubed) PCNL.

| Study | Type of PCNL | Number | Cost (mean ± SD) in US$ |
|---|---|---|---|
| Bellman et al. [41] | Standard | 50 | 3750 |
| | Tubeless with stent | 50 | 1638 |
| Feng et al. [42] | Standard | 10 | 7555 ± 619 |
| | Mini-PCNL | 9 | 6565 ± 300 |
| | Tubeless with stent | 8 | 5562 ± 356 |
| Choi et al. [43] | Standard | 49 | 2846 ± 824 |
| | Totally tubeless | 44 | 2380 ± 549 |

There is a clear need for more prospective studies investigating the cost-effectiveness of PCNL, URS, and SWL for the treatment of renal stones, especially given the expanded use of URS to treat large renal stone burdens and increasing use of tubeless and mini-PCNL. Future research should account for both stone size and stone location for determining relative cost-effectiveness among these treatment modalities.

## Medical evaluation and management

Dietary and medical management aimed at reducing stone recurrence seems desirable given the rising prevalence of stone disease. While dietary modification has been shown to be effective at reducing recurrence and comes at little to no added cost, it does so to a lesser extent than medical therapy, which has been shown to decrease stone recurrence compared to no treatment [45]. When making decisions regarding the need for stone prevention clinicians must weigh the costs of medical therapy along with potential side effects and the effects of lifestyle changes against the idea that not all recurrent stones are symptomatic or require treatment. Numerous authors have investigated the economic consequences of these approaches to better understand these conflicting outcomes.

An early study evaluating medical therapy was performed by Parks and Coe [46]. The authors calculated the cost savings of metabolic evaluation and medical treatment by comparing rates of stone occurrence before and after the initiation of medical therapy. All patients received initial extensive laboratory evaluation and counseling on dietary modifications aimed at minimizing lithogenic risk factors. Select patients were prescribed medications such as allopurinol, potassium citrate, and thiazides based on metabolic background. This approach produced a stone remission rate of 83%. By applying this remission rate, along with estimates of rates of stone passage events, cost of surgical procedures, and need for hospitalization, they estimated that their preventative regimen resulted in an average cost savings of $1162–3162/patient/year. This result is likely an overestimate due to absence of systematic incorporation of dietary measures in the control group, which have been shown to reduce recurrence rates [47–49], until after entry into the stone clinic. It is important to point out there was no true control group in this study, and pretreatment stone incident rates were based on patient recall, which is subject to bias.

Disease aggressiveness certainly plays a role in the decision to initiate dietary and/or medical therapy. Lotan et al. performed a cost analysis (decision-tree modeling) to compare the costs of six different treatment strategies: dietary measures only (conservative), empiric drug therapy (empiric), or directed drug treatment based on simple (SMEM) or comprehensive (CMEM) metabolic evaluation with either all patients undergoing drug treatment (SMEM or CMEM) or only selected patients with diagnosed metabolic abnormalities receiving drugs (modified SMEM and modified CMEM) [50]. The model accounted for accrual of cost for evaluation, drugs, emergency treatment, and surgical treatment for recurrent stones.

Conservative therapy was the most cost-effective strategy for first-time stone formers, resulting in a recurrence rate of one stone episode every 14 years. Conservative therapy was also the least costly approach for recurrent stone formers, but it was associated with an excessively high recurrence rate of 0.3 stones/patient/year. As expected, each of the four drug treatment strategies were all more costly than dietary measures alone ($885–1187 vs. $258/year for the conservative approach), but the benefit was that drug treatment further reduced recurrence rates by 60–86% compared to conservative therapy. Modified SMEM was slightly more costly and marginally more effective than empiric therapy. Modified CMEM had little or no improvement in efficacy over modified or empiric SMEM with equivalent or greater cost. This data can be seen in Table 72.5 [50].

**Table 72.5** Model outcomes by treatment strategy.

| Strategy | Stone formation rate (stones/patient/year) | Model cost ($/year) |
|---|---|---|
| First-time stone formers | | |
| Conservative | 0.070 | 133 |
| Empiric | 0.013 | 966 |
| Modified SMEM | 0.011 | 1085 |
| SMEM | 0.028 | 835 |
| Modified CMEM | 0.009 | 1170 |
| CMEM | 0.015 | 1087 |
| Recurrent stone formers | | |
| Conservative | 0.300 | 258 |
| Empiric | 0.057 | 990 |
| Modified SMEM | 0.048 | 1104 |
| SMEM | 0.120 | 885 |
| Modified CMEM | 0.041 | 1187 |
| CMEM | 0.065 | 1114 |

CMEM, comprehensive metabolic evaluation; SMEM, simple metabolic evaluation. For details about the treatments, see text.
*Source:* [50]. Reproduced with permission of Elsevier.

Significant improvements in recurrence rates (by up to 60%) were observed with treatment strategies in which all patients received medication, regardless of metabolic abnormalities, compared to strategies where only patients with a 24 hour urine abnormality were prescribed drugs. Moreover, since CMEM significantly increased the cost of treatment without added efficacy, the results recommend modified SMEM in which all patients received either drug treatment or empiric therapy. Interestingly, since the least costly approach (conservative therapy) was associated with an disappointingly high recurrence rate, this model demonstrated the benefit of treating every recurrent stone former with medication despite the relatively high drug costs, due to the associated significant reduction in rate of recurrence.

Decision-tree analysis has also been used to evaluate the cost-effectiveness of medical evaluation and treatment strategies across healthcare systems. Lotan et al. created a model using data derived from a published international cost survey to determine the most cost-effective strategy for countries for which data was available [6, 51]. Treatment arms were limited to conservative therapy, empiric treatment, and comprehensive metabolic evaluation with targeted medical therapy for patients with a metabolic abnormality. For first time stone formers, conservative (dietary) therapy alone was the most cost-effective strategy in all 10 countries. The most cost-effective strategy for recurrent stone formers in all countries except the UK was conservative therapy, followed by empiric therapy and then directed therapy. Empiric therapy was the least costly strategy in the UK that enjoyed a low cost of drug therapy (at the time estimated at only $29/patient/year). Similarly, in other countries with relatively low medication costs, like Switzerland and Turkey, there was a marginal cost difference between conservative and empiric therapy; however, empiric therapy produced a significant improvement in efficacy. Two-way sensitivity analysis demonstrated that more than one stone episode per year would be necessary to render empiric therapy cost superior to conservative therapy in all analyzed countries except Switzerland and the United Kingdom. In countries with high drug costs, like the United States, conservative therapy naturally offered an even greater cost advantage. Use of metabolic evaluation to direct medical therapy was not cost-effective in any of the countries studied since the model had little difference in efficacy between empiric and targeted medical therapy.

International cost analyses make it clear that differences in medication costs and surgery across healthcare systems, predominantly based on subsidization, drive differences in the cost-effectiveness of medical management treatment schemes. Drug therapy is favored when medication costs are low. A conservative approach is favored when medication costs are higher, due to relatively less frequent need for surgical treatment of stone recurrences and fixed reimbursement for surgical procedures.

## Conclusion

Delivering high-quality, cost-effective healthcare is more important now than ever before. For stone disease, cost can be scrutinized at every step of care, from diagnosis to decisions about observation versus treatment and subsequent need for medical prevention. While cost-effectiveness is certainly important when considering care in the abstract sense, medical and surgical treatment decisions should always be made with best interests and safety of the patient in mind. This may result in a treatment selected to maximize stone clearance compared to another outcome and in the process result in higher cost. Going forward, new comprehensive cost analyses and cost-effectiveness studies will help clinicians further refine and improve stone treatment.

## Introduction

Ureteral stents are widely used in urologic clinical practice. The efficacy of ureteral stents in the management of various urologic conditions causing upper urinary tract obstruction has been extensively proven and their contribution to urology remains enormous. Ureteral stents are available in various shapes and made of various materials. Ureteral stents can be divided into polymeric stents (PSs) and metal mesh stents (MSs). PSs are usually composed of polyurethane and silicon-based polymeric biomaterial. A unique category of PSs is the biodegradable stents which are composed of biomaterials such as poly-L-lactide-co-glycolide (PLGA) or L-lactide-glycolic acid copolymer. MSs are based on metal alloys such as MP35N (a nonmagnetic nickel–cobalt–chromium–molybdenum alloy), nickel-cobalt, or stainless steel. Stent designs depend on their use and composition. The most commonly used PS design is the double-pigtail (double-J) design, which is characterized by coil-shaped stent ends. MSs are either MSs identical to those used in coronary vessels or double-J stents composed of metal wire (Resonance, Cook Urological) [1].

Regardless of the stent design and composition, the use of ureteral stents is associated with several complications, which limit their use and necessitates the escalation of research towards the introduction of the "ideal" ureteral stent. The properties of the ideal stent include the ability to hold its position (memory) over time (durometry), easy manipulation of its shape (elasticity), and excellent tensile strength while having elongation capacity. Moreover, placement of the ideal ureteral stent should not be associated with degradation of its structure and function (biodurability) or influence the urothelium (biocompatibility). The ideal stent should be radiopaque and therefore visualized by fluoroscopy [1, 2]. Patient comfort and resistance to bacterial colonization could also be considered important properties of the ideal stent. The ideal stent is currently not available and the problems related to ureteral stenting remain an issue, especially in cases requiring long-term stenting to maintain ureteral patency.

## Indications for ureteral stents

The insertion of stents in the ureter serves several purposes: relief of ureteral obstruction, promotion of ureteral healing, and prevention of possible complications. Postoperative nephrostomies are usually avoided by the use of ureteral stents. The stent acts as a scaffold for the growth of epithelium, promotes ureteral healing by aligning the ureteric wall, and reduces extravasation around the ureter (less inflammation) [3, 4].

The use of ureteral stents for the management of stone disease provides obstruction/hydronephrosis relief, and reduction of colic and infection incidents. Double-pigtail PSs are inserted in lithiasis patients for temporary management of stone-related obstruction [5]. An absolute indication for the management of stone cases by ureteral stenting is the concomitant presence of ureterolithiasis and active infection [6]. The routine use of double-pigtail PSs after shock-wave lithotripsy (SWL) and ureteroscopy (URS) remains questionable [7, 8]. Transplantation-related ureteral strictures are an indication for PS insertion [9–11]. Partial ureteral lacerations are successfully managed by double-pigtail stent placement [12], as are ureteropelvic junction obstructions (UPJOs); this provides relief of flank pain and healing of the repaired site after pyeloplasty and endopyelotomy [4, 11]. PSs are

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

also inserted intraoperatively in reconstruction of the ureter to, as mentioned above, provide alignment of the area of the anastomosis and act as scaffold around the ureter, which may eventually facilitate the healing process. Moreover, the presence of a ureteral stent minimizes urine extravasation and reduces ureteral wall edema [4]. Ureteral stents make a significant contribution to the treatment of ureteral fistulas: 85% of such cases are efficiently healed with the use of a PS [12].

Malignant ureteral obstruction remains a challenging field for PSs. Despite the use of PSs as an alternative to nephrostomy tubes in the above cases, extrinsic malignant ureteral obstruction managed by PSs is associated with high failure rates [13, 14]. Two ipsilateral pigtail ureteral stents were proposed as a method to address cases of single stent failure, with various success rates. A double-lumen double-pigtail stent has also been introduced and evaluated with promising results in a pig model [5, 15].

MSs have been used for the management of extrinsic malignant ureteral obstruction in cases where PSs have failed. The reported success rates were high and the method proved to be useful [2]. The use of MSs has expanded in benign cases of ureteroileal anastomotic strictures and UPJO, with promising success rates. In fact, long follow-up of the former indicates that MSs are an alternative to challenging reintervention procedures performed for ureteroileal anastomotic strictures and UPJO [2, 15, 16].

## Complications of ureteral stents

Long-term urinary drainage by ureteral stent insertion is limited by several complications. These complications are related to the design and material of the stent. Major problems of stent use include infection, patient discomfort, encrustation, migration, and hyperplastic reaction.

### Stent syndrome

The “stent syndrome” represents the most common double-pigtail PS-related complication and is characterized by irritative voiding symptoms, flank pain, suprapubic discomfort, and occasional hematuria [4, 5]. Urinary system symptoms may be present in up to 80% of patients with stented ureters. Bladder pain (80%) and incontinence (60%) are important problems for these patients [17]. Insertion technique and stent characteristics are unrelated to these symptoms, while selection of the appropriate stent length is related to reduced morbidity [4, 18, 19]. Voiding symptoms, such as urgency and dysuria, attributed to irritation of the bladder floor by the stent, were significantly more frequent in patients with longer stents [20]. Nevertheless, flank pain was not reduced by the stent length as this symptom is related to vesicoureteric reflux [22]. Softer or tapered lumenless tails have been also proposed for symptoms reduction [21, 22]. Recently, the concept of replacing the distal coil of the double-pigtail PS stent with a 0.3 Fr suture was evaluated. The suture is left in the bladder and facilitates removal. Moreover, the presence of less foreign material in the bladder was theorized to result in reduced lower urinary tract symptoms. A prospective study on 79 patients showed that this design significantly reduced urinary symptom score and pain score [23].

### Stent migration

Several factors affect stent migration including stent length, material, and diameter [24, 25]. Migration of the PSs is associated with stent design. Double-pigtail stents are less prone to migration in comparison to single-pigtail stents. PSs usually migrate towards the kidney rather than towards the bladder [26]. Proximal stent migration is less common with an incidence of 1–4.2%; the management of these cases could represent a greater challenge in comparison to the distal migration [27–29]. When the distal end is below the pelvic brim it could be managed with the use of URS, a stone basket, or a Fogarty catheter with success rates reaching 90% [30]. A percutaneous approach might be more successful than the retrograde retrieval in special circumstances including cases of proximal migration above the pelvic brim, migration above a stricture, or a recent ureteral repair [31]. Covered MSs have been associated with rates of migration up to 81.2% [32].

### Encrustation

Encrustation is a major problem encountered in long-term ureteral stenting with both PSs and MSs. The risk of encrustation is associated with both the stent biomaterial and the patient’s history. Stent encrustation in urolithiasis patients occurs in 9.2% of stents removed in under 6 weeks, 47.5% of stents removed between 6 and 12 weeks, and 76.3% of stents removed after more than 12 weeks [28]. Kawahar et al. observed that stents smaller than 6 Fr were significantly more likely to encrust than those 7 Fr or larger [33]. Other risk factors for stent encrustation include urinary tract infection or urosepsis, history of stone disease, pregnancy, urinary diversions, metabolic or congenital abnormalities, and chronic renal failure [34–36]. Encrustation is always related to biofilm formation despite the absence of evident urinary infection. Biofilm is formed by adhesion of microorganisms on the stent surface and gradual development of a thin film of extracellular matrix around them [37]. Biofilms and urease-producing organisms on a stent surface induce elevation of urinary pH and precipitation of salts such as calcium hydroxyapatite and magnesium ammonium phosphate. The latter process eventually results in struvite and calcium phosphate accumulation [38]. The subsequent encrustation and infection of stents may be responsible for pain, hematuria, and sepsis [39]. The phenomenon of encrustation makes routine exchange of PSs necessary for the prevention of related complications. "Stone formers" are difficult to manage because the exchange intervals are unpredictable [4]. Many algorithms have been proposed for the classification and management of encrusted stents. The suggested management modalities include URS, percutaneous nephrolithotomy, extracorporeal SWL, and cystolitholapaxy [40–42].

Encrustation of MSs is associated with the aperistaltic segment of the stented ureter in conjunction with ureteral peristalsis and urinary stasis, resulting in encrustation of the areas of the MS uncovered by urothelium [43]. An encrustation-resistant MS needs to be made of a biomaterial resistant to bacterial infection and subsequent biofilm formation. In addition, it should be easily covered by endothelial cells and become incorporated into the ureteral wall [44, 45].

### Urothelial hyperplasia

Urothelial hyperplasia is a significant complication of MS insertion in the ureter. Ureteral patency can be compromised by the development of hyperplastic tissue protruding through the stent struts. The hyperplastic tissue is responsible for restenosis of the stented ureter. An experimental study in a porcine model by Desgrandchamps et al. revealed that only one of eight stents was patent 35 days after insertion [45]. It appears that hyperplasia can be prevented by avoiding overextension of the strictured area of the ureter, followed by careful stent implantation. It should be noted that urothelial hyperplasia regresses within 4–6 weeks of MS insertion, resulting in ureteral lumen narrowing [46–50]. Flueckiger et al. suggested that the initial effect (first 1–2 weeks) of the inserted MS in the ureter is reactive swelling of the ureter and not hyperplasia of the urothelium leading to constriction of the ureteral lumen [51]. A characteristic trumpet-like morphologic configuration of the ureter located on the upper extremity of the stent has been described, but is not related to ureteral patency risk [27, 50].

## Polymeric stents

PSs are the most commonly used ureteral stents. A variety of synthetic polymeric compounds has been used for the manufacture of PSs. These materials are based on polyurethane or silicone, such as Silitek (Surgitek, Medical Engineering Corporation, Racine, WI, USA), C-Flex (Cook Urological, Spencer, IN, USA), and Percuflex (Boston Scientific, Natick, MA, USA) [52, 53]. Silitek is a block copolymer based on silicon, while C-Flex is a proprietary silicone with styrene/ethylene/butylene block copolymer. Percuflex is composed of an olephinic block copolymer. In contrast, Tecoflex (Thermedics, Woburn, MA, USA) is a proprietary aliphatic thermoplastic and is not based on silicone or polyurethane. Polyurethane is a relatively cheap material and has the advantage of high versatility, but its biocompatibility is considered poor and it is related to significantly more urothelial ulceration and erosion [54]. The gold standard of biocompatibility is silicone [55]. Although all the polymeric materials described above are susceptible to encrustation, Siliteck, C-Flex, and Tecoflex are less frequently affected by this complication. Moreover, polyurethane, Silitek, and Percuflex provide high tensile strength [53].

### Double-pigtail polymeric stents

The efficiency of retrograde ureteral stenting in obstruction of extrinsic and intrinsic etiology has been reported by Yossepowitch et al. [56]. Extrinsic obstruction was associated with a higher degree of hydronephrosis and the site of obstruction was located more distally. Ureteral stents achieved successful alleviation of the obstruction in 94% and 73% of patients with intrinsic and extrinsic obstruction, respectively. Intrinsic obstruction cases were successfully managed at 3 month follow-up, while extrinsic ureteral obstruction was successfully relieved in only 54.6% of the stents after the same time period. Other investigators reported a success rate for retrograde stenting of intrinsic ureteral obstruction of 88%. The mean follow-up was 25.5 months [57]. The experience gained by the same investigators with the management of extrinsic ureteral obstruction by retrograde stenting revealed success rates of 81, 85, and 100% for malignant, retroperitoneal fibrotic, and benign-etiology obstruction, respectively. Average follow-up was 16 months (range 0.7–98 months) [58].

A large experience with 2431 patients (2685 ureters) who were treated by double-pigtail stent insertion has been recently published [59]. The majority of the indications for ureteral stent insertion were URS or percutaneous lithotripsy, SWL, and open lithotomy. Iatrogenic ureteral injury, extrinsic ureteral obstruction, UPJO, and ureterocysteoneostomy were also managed by double-pigtail stent insertion. Several complications were observed: pain, gross hematuria, bladder irritation, high fever, encrustation, stent migration, and stenosis (or recurrence of stenosis). The mean follow-up period was 31 ± 1.9 days (range 1–123 days). As a result, the insertion of double-J stents for endoscopic and open procedures for upper urinary tract diseases can be considered as a safe and efficient method, at least for up to 4 months.

The long-term outcome of double-pigtail ureteral stenting for the management of extrinsic ureteral obstruction was evaluated by Rosevear et al. in a study including experience accumulated over 9 years [58]. In total, 54 patients (87 ureters) with malignant, retroperitoneal fibrosis, or benign tumors were successfully treated in 81, 85, and 100% of cases, respectively. The mean follow-up period was 16 months (range 0.7–27 months) and mean interval between stent exchanges was 3.6 months. The average interval to stent failure was 4.8 months (range 0.7–27 months).

Quality of life is an important issue for patients with ureteral stents as the stent-related complications may have a significant impact. Joshi et al. investigated the effect of ureteral stents on quality of life and associated urinary symptoms. Storage symptoms, bladder pain, and hematuria were the most common symptoms observed, and at least one symptom was encountered in 80% of patients. In addition, the available questionnaires did not elucidate the entire range of symptomatology [60].

A coil-reinforced polymeric double-pigtail stent has been recently introduced for the treatment of malignant ureteral obstruction. The Silhouette stent (Applied Medical, Rancho Santa Margarita, CA, USA) has been introduced due to the high failure rate of common polymeric ureteral stents [5]. The stent proved to be more resistant to extrinsic compression than the also newly introduced double-J all-metal Resonance [60].

A unique double-pigtail stent is the Zebra (Neo Medical, Bruckmühl, Germany). It is a Teflon-coated lumenless double-pigtail stent, which facilitates passage of residual stone fragments through the ureter. Comparison of Zebra to standard PSs in two stone-forming patients who underwent SWL revealed no ureteral damage, and after 4 and 5 weeks there was no encrustation on the Zebra stent, while the standard PSs were covered by considerable encrustation [61]. Moreover, the material fatigue evaluation of the Zebra stent in an experimental model simulating the movement of the ureter estimated that the stent would not break even if it was left indwelling for 9 months [62].

#### Ipsilateral and dual-lumen double-pigtail polymeric stents

The use of two ipsilateral double-pigtail PSs for the management of extrinsic ureteral obstruction resistant to a single stent insertion was proposed more than a decade ago [63]. This stent configuration has been referred to in the literature as "tandem ureteral stents" (TUS). The first report included five patients who were treated for ureteral obstruction due to ureteral orifice stricture, retroperitoneal fibrosis, and middle-ureter stricture. These patients were managed successfully by the insertion of two ipsilateral 7 Fr ureteral stents, which were exchanged at 3 month intervals until the patients were managed surgically [63]. In a subsequent report, malignant ureteral obstruction in seven patients was managed by the insertion of two ipsilateral stents [64]. Previous insertion of a single double-pigtail stent had been unsuccessful in the management of the obstruction. Three patients died within 3 months of insertion of the two ipsilateral stents, while the remaining four had a mean follow-up of 16 months (38 months maximum). Stents were exchanged every 4–6 months to avoid long-term complications. Recently, Elsamra et al. published the largest series in TUS. TUS insertion or exchange was performed in 187 cases. The latter cases included 39 renal units with malignant ureteral obstruction and 36 units with benign ureteral obstruction. Stent failure was noted in 12.8% of patients with malignant ureteral obstruction and none in the benign ureteral obstruction cases. The investigators proposed that TUS are highly successful in both benign and malignant causes of obstruction [65]

A novel dual-lumen double-pigtail stent composed of two adhered ureteral stents has been evaluated in a porcine model. The stent provides better flow in comparison to a single ureteral stent. The main advantage of this stent is that its insertion requires only one guidewire, whereas insertion of two ipsilateral stents requires two guidewires, making the procedure more cumbersome, Clinical experience with this interesting stent has not been reported since its experimental evaluation [15].

#### Coil-reinforced double-pigtail polymeric ureteral stent, the Silhouette stent

The coil-reinforced double-pigtail PS Silhouette stent is a new metal stent that has been tested *in vitro* studies. These showed that the stent can resist higher compressional forces than the Resonance stent and is less prone to kinking than other stents, and hence has a lower rate of failure [66, 67]. Nevertheless, clinical data are not currently available to evaluate the efficacy of this PS.

### Biodegradable polymeric stents

Biodegradable polymeric materials and stents have been present in urology for over a decade. Their main advantage is that they do not need to be removed. The additional procedure for the extraction of the inserted stent is not necessary, the complications of this procedure are avoided, and the period of discomfort for the patient is shortened [5, 53].

In a porcine model, a PLGA ureteral stent inserted after experimental Acucise™ balloon incision endopyelotomy was shown to provide similar drainage to a standard PS (Applied Medical) in pigs, but its biocompatibility was not favorable compared to a standard stent since the musculature of the incised ureteral segments revealed inferior healing [68].

A biosolvable ureteral stent (TUDS, Boston Scientific) was evaluated in terms of biodegradation and biocompatibility in a porcine model. The stent is designed to maintain ureteral patency for 48 hours, after which it softens and eventually degrades. Histologic results were similar for both a standard hydrogel-coated stent and TUDS [69]. The clinical assessment of the TUDS stent showed safe and efficient drainage. Dissolution took place in 90% of the stents after an average of 8 days. Satisfaction was reported by 89% of the patients treated by TUDS [70].

Tajla et al. evaluated a horn-shaped helical PGLA stent that was used for the postoperative management of antegrade endopyelotomy (cold-knife technique) performed for UPJO [71]. *In vitro* studies estimated the degradation time for the stent to be 2–2.5 months. Percutaneous nephrostomy or stent removal procedures were not deemed necessary for the treated patient. The stent contributed to the reduction of vesicoureteral reflux and postoperative renal infection due to its function as a partial catheter.

Uriprene is a biodegradable copolymer composed of L-glycolic acid, polyethylene glycol, and barium sulfate which has been recently considered for use in PSs. *In vivo* studies in porcine models of uriprene stents showed promising preliminary results. These stents resulted in lower inflammatory response compared to conventional PSs and successfully degraded after 4 weeks [72–74].

Newer biodegradable substances are also under investigation. Novel substances include the tocopherol acetate and the magnesium yttrium biodegradable alloy which seem to possess antibacterial characteristics and have been tested *in vitro* [75–77]. Another biodegradable stent comprising polysaccharides of natural origin was recently described by Barros et al. [78]. These stents contained different blends of gellan gum, gelatin, and alginate and were tested in in artificial urine. The stent degraded between 2 weeks and 2 months with the ability to control degradation rate by altering the ratio of biodegradable materials. The ability to resist bacterial adherence was evaluated and compared to a plastic biostable stent as a control. The comparison showed that there was no difference in bacterial adherence between the described biodegradable stent and the control. In addition, no encrustation was observed within the tested time frame [78]. Considering the above, the field of biodegradable stents seems to be promising for stents that could be used for long-term stenting of the ureter without significant complications. In addition, the need for removal of the stent may be diminished.

## Drug-eluting and drug-coated polymeric stents

Polymeric ureteral stents that are coated with pharmaceutical substances or release drugs from their surface to the surrounding tissue have been introduced and clinically tested. Triclosan is a broad-spectrum antibacterial and antifungal agent that has been reported to inhibit the growth of common bacterial uropathogens *in vitro*, and is thus considered useful for the reduction of urinary tract infection and subsequent encrustation of an indwelling stent [79]. A significant decrease in *Proteus mirabilis* growth and survival was observed in a rabbit experimental model when a triclosan-eluting ureteral stent was inserted in the urinary system (bladder) [80]. In eight patients significantly fewer antibiotics were administered, and there was a slightly higher number of positive urine cultures, but significantly fewer symptomatic infections with long-term use of the triclosan-eluting stent. Bacterial resistance to triclosan was not noted during the 3 month follow-up period [81]. Mendez-Probst et al. evaluted triclosan-eluting stent in a randomized prospective study. They compared the triclosan-eluting stent with a non-eluting stent (control). The triclosan-eluting stent group didn't receive any antibiotics and the control group received 3 days of prophylactic levofloxacin. The results showed no significant differences in the infection rate or encrustation. Nonetheless, triclosan-eluting stents showed to significantly decrease ureteral-stent-related symptoms [82].

Ketorolac-eluting stent was evaluated for its short-term efficacy in a double-blind randomized multi-institutional clinical trial [83]. The 276 patients included were divided into two groups (triclosan stent and conventional stent). There were no significant differences in primary and secondary intervention rates between the two groups. Fewer patients with the ketorolac-eluting stents used pain medication in comparison to the control group.

A heparin-coated double-pigtail ureteral stent was introduced in an attempt to minimize microbial adhesion, biofilm formation, and subsequent encrustation of long-term indwelling stents in the urinary tract. In five patients, a heparin-coated ureteral stent was inserted in one ureter and a conventional double-pigtail stent in the other for a month [84]. The thickness of the encrustations observed by electron microscopy on the heparin-coated stents was significantly less compared to that on the conventional ureteral stents. Moreover, the encrustation on the heparin-coated stents was less uniform and more compact. Two heparin-coated stents were left indwelling in long term (10 and 12 months) and on removal showed no evidence of encrustation and an unchanged heparin layer.

## Metal mesh stents

### Self- and balloon-expandable metal mesh stents

MSs used in the ureter can be divided into four general groups: self-expandable, balloon-expandable, covered, and thermo-expandable shape-memory stents. Covered MSs were introduced in an attempt to minimize tissue ingrowth, which eventually compromises ureteral patency [27]. MSs implanted in the ureter for the management of various malignant and benign diseases are the Wallstent (Microvasive, Natick, MA, USA), Memokath 051 (PNN Medical, Kvistgaard, Denmark), self-expanding polytetrafluoroethylene-covered nitinol stent (Hemobahn Endoprosthesis, W.L. Gore and Associates, Flagstaff, AZ, USA), and the recently introduced all-metal double-pigtail Resonance stent.

The Wallstent is composed of braided biomedical cobalt-based alloy monofilaments and is the most extensively used self-expandable endoprosthesis in the ureter [1]. Inserted in the ureter it appears to represent a safe and effective method for the palliative treatment of malignant ureteral strictures. Benign and malignant ureteral strictures in patients not suitable for surgical treatment were treated with the Wallstent by Pollak et al. [85] One of six stented ureters were patent after 11 months. In two patients, three stents were implanted for the palliative management of malignant disease and were patent up until death (3–5 months after implantation). Ingrowth of hyperplastic and granulation tissue was responsible for the occlusion of all stents inserted for benign strictures, while tumor ingrowth and granulation tissue were observed in malignant cases. Wallstent endoprosthesis proved to be ineffective for long-term drainage in patients with benign ureteroenteric strictures. The mid-term clinical outcome of the Wallstent self-expandable stent implantation for the management of malignant ureteral obstruction was evaluated in 40 patients with 54 malignant ureteral obstructions [49]. Patency was confirmed in 51 of the stented ureters during the mean follow-up period of 10.5 months (range 1–44 months). Almost half of the ureters (49%) required additional procedures to maintain patency. Adequate drainage preventing hydronephrosis was observed in the majority of the cases and major complications were not encountered.

Malignant ureteral strictures due to gynecologic cancer were managed in 14 patients with self-expandable MSs in a report by Barbalias et al., and ureteral obstruction was relieved in all cases [50]. The mean follow-up time was 15 months (range 9–24 months). Tumor ingrowth requiring additional coaxial stent placement and borderline tumor overgrowth was observed in one case each. Urothelial hyperplasia was noted in all stented ureters and additional retrograde insertion of a double-pigtail stent was deemed necessary for a 1 month period. On the proximal edge of the stent, a mild ureteral narrowing was noted (trumpet-like configuration), which did not impact ureteral patency. The trumpet-like configuration was a constant finding during the follow-up period. The authors concluded that the implantation of self-expandable MSs is a safe and effective method for by-passing gynecologic malignant ureteral obstruction.

The combination of self-expandable MSs with coaxial double-pigtail stents was proposed by Hekimoglu et al. [39]. Ten ureters (10 patients) with malignant obstruction were treated with this combination. The double-pigtail stents were removed in seven patients 2 and 3 months after the implantation. Six patients developed hydronephrosis and double-pigtail stents were reinserted. PS exchange was performed at 3 month intervals. The MS lumen was compromised by hyperplastic tissue and encrustation. Nevertheless, this combination was adequate to achieved internal urinary drainage.

Several authors have reported promising results with the management of ureteroileal anastomotic strictures by MS insertion [2, 5, 86–93]. In these reports between one and 18 patients were treated, while the number of treated ureteroileal strictures ranged between one and 24. The mean follow-up period ranged from 6 to 22 months. Stricture recurrence was observed by the majority of the authors. Our group reported long-term results in 18 patients with ureteroileal anastomotic strictures who were managed with MS placement [2]. Mean follow-up was 21 months (range 7–50 months). The technical success rate of stricture crossing and stenting was 100%. Immediate poststenting patency rate was 70.8% (17 of 24 cases), while primary patency rates at 1 and 4 years were 37.8 and 22.7%, respectively. Fifteen stented ureters required secondary interventions. Secondary patency rates were 64.8 and 56.7% at 1 and 4 years, respectively. Periodic exchange of external–internal double-pigtail catheters until the end of the follow-up period was performed in six ureteroileal conduits. Definitive treatment for the ureteroileal strictures was achieved by MSs in more than half of the cases. The remaining cases were managed by regular exchange of double-J catheters in retrograde fashion. Surgical revisions of ureteroileal anastomotic strictures are challenging, while MS implantation provides efficient drainage while preserving the quality of life.

Barbalias et al. have proposed the use of self-expandable MSs for the management of UPJO [16]. MSs were placed in four patients who had previously undergone open pyeloplasty and in whom recurrence of UPJO was diagnosed. The mean follow-up period was 16 months (range 9–24 months). The placement procedure was successful in all cases and patency was confirmed in all four patients. Ingrowth of fibrotic tissue through the stent led to additional coaxial overlapping MS insertion in one patient 2 months after initial stent placement. The results were promising and the authors suggested the performance of more extensive clinical trials in order to validate this application of MSs.

Balloon-expandable stents have not been extensively used in the ureter. Barbalias et al. treated six patients with malignant disease with self-expanding stents and six with balloon-expandable stents [46]. Additional interventions were deemed necessary in three cases due to urothelial hyperplasia, tumor ingrowth, and local recurrence of primary cancer invading the upper end of the ureter. Mean follow-up was 9 months (range 8–16 months).

The Memokath 051 represents a unique type of MS. It is a thermoexpandable shape-memory stent composed of nickel and titanium alloy. It has a tight spiral structure, which prevents urothelial growth [94]. The Memokath 051 softens below 10 °C and regains its shape when reheated to 50 °C. The thermal shape memory feature makes the removal of the stent possible. Kulkarni and Bellamy have used the endoprosthesis for the management of ureteral obstruction of both benign and malignant etiology [95]. Long-term results for the management of malignant and recurrent benign strictures are available: 18 malignant and 10 recurrent benign cases were treated with the Memokath 051 and followed up for a mean of 19.3 months (range 3–35 months). At the end of the follow-up period, 15 stents (13 patients) provided adequate drainage, while eight patients carrying 13 functioning stents had died. Infection and migration were not observed. In general, the Memokath 051 proved to be advantageous over conventional double-J catheters. Moreover, the potential for removal of the stent due its thermal memory was a significant advantage over conventional MSs. This removal capability was not a feature of any other MS until the introduction of the Resonance double-pigtail MS.

Such favorable results with the Memokath 051 were not reported by Klarskov et al., who used it to treat 37 stenosed ureters (33 patients) attributed to both malignant and benign conditions [96]. The mean follow-up period was 14 months (range 3–30 months). Migration towards the bladder was observed in 10 stents and 12 stents malfunctioned, giving a total of 22 nonfunctioning MSs. Encrustation resulted in occlusion of four stents at intervals after stent insertion ranging between 1 and 10 months. In other studies, a need for stent reinsertion or manipulation was reported in 20–25% of patients. Long-term complications of the Memokath 051 were noted to be encrustation in 3–5% and stent migration in 15–18% [97, 98].

Li et al. evaluated a titanium–nickel alloy-based self-expandable stent in benign ureteral strictures over a long mean follow-up period of 92 months (range 12–131 months) [99]. Encountered complications included hyperplastic reaction, infection, and encrustation with stone formation. The investigators concluded that MSs could adequately manage selected cases of ureteral strictures.

Recently, we reported our 10 year experience with metal mesh stenting for the management of malignant ureteral obstruction [100]. Ninety patients (119 ureters) with ureteral obstruction from various pelvic and metastatic tumors were treated with several different types and brands of MSs in an attempt to provide long-term urinary drainage without requiring nephrostomy tubes, and followed up for a mean of 15 months (8–38 months). Hyperplastic reaction and/or tumor ingrowth resulting in tissue protruding through the stent struts and obstructing the stent lumen were the most common problems and were addressed by repeat balloon dilations. Those cases resistant to balloon dilation were managed by insertion of a double-pigtail stent coaxially, which ensured ureteral patency. With primary and secondary patency rates of 51.2 and 62.1% it was concluded that metal mesh stenting of the ureter should be carefully considered for long-term urinary drainage.

## Covered metal mesh stents

Covered MSs were introduced as a solution to the urothelial hyperplasia compromising the patency of conventional MSs. The high migration rate (81.2%) of covered MSs, which could induce renal colic, represented a major problem in clinical application and minimized further use of these stents in the urinary tract. The inability of covered MSs to anchor into the ureteral wall was associated with the coating material and the enhanced ureteral peristalsis [27]. Migration was managed by cystoscopic removal of the migrated covered stents and the coaxial insertion of bare stents.

Recently, an S-shaped covered MS was introduced and underwent comparative evaluation to bare MSs in the canine ureter. The shape of the stent was responsible for the anchoring into the ureteral wall. The stent was covered with polytetrafluoroethylene (PTFE) for prevention of lumen occlusion due to hyperplastic reaction. Both migration and the hyperplastic ureteral obstruction were avoided [101]. In an attempt to reduce urothelial hyperplasia, a study group recently evaluated the additive effects of placing a PS together with a MS in the management of obstructive uropathy in animal model. The PS is inserted through the MS in order to maintain the patency of the latter stent. The one group underwent covered MS and PS placement. The other group received the same MS without a PS. Although there was no significant difference in the development of urothelial hyperplasia, the group with the combination of PS and MS showed a significantly lower degree of obstruction severity due to hyperplasia [102].

Allium (Allium Medical Solutions Ltd, Caesarea, Israel) and the UVENTA (Taewoong Medical Co. Ltd, Gyeonggi-do, South Korea) stents,which are specially designed for the urinary tract-covered MSs, have been recently introduced [103, 104]. The Allium stent is composed of nitinol and is covered with PTFE to avoid tissue ingrowth inside its lumen and early encrustation. It has an intravesical anchor to prevent migration. Moskovitz et al. inserted the Allium stent in 49 cases with a history of malignant disease [103]. Perioperative complications were not observed. Over a mean follow-up time of 21 months (range 1–63 months) stent migration occurred in 14.2% and only one case of stent occlusion was noted. Other investigators evaluated the Allium stent in 12 benign cases of ureteral obstruction and achieved patency in all cases without intraoperative complications [105].

The UVENTA stent has a PTFE-membrane-covered metal mesh to avoid tissue ingrowth and hence prevent hyperplasia related obstruction. The design of the stent also aim to prevent any migration [43]. Kim et al. [104] published their experience with the use of UVENTA stent in 18 patients with malignant ureteral obstruction. During a mean follow up of 7.3 months no obstruction of the stents occurred. In addition, hyperplastic reactions, migration or encrustation were not observed. Chung et al. evaluated UVENTA over a 10 month follow-up period and reported a primary patency rate of 64.8% and a secondary patency rate of 81.7%. Stent failure was predominantly a result of tumor progression at an adjacent ureteral segment. Stent migration was not reported [106]. Another study evaluated the efficacy of the UVENTA in comparison to Memokath 051 [107]. It showed that UVENTA had a higher clinical success rate over the Memokath 051 in benign and malignant obstructions. A multicenter study compared the efficacy of UVENTA with PS insertion for the management of 42 malignant ureteral obstructions. The study showed that the UVENTA was superior to the PSs in terms of technical success and patency [108].

### Double-pigtail metal stents (Resonance)

The Resonance stent was recently introduced as an all-metal double-pigtail stent. It is composed of MP35N alloy in a tight spiral structure. Ureteral obstruction, due to either malignant or benign conditions, can be managed with Resonance [109–112]. Borin et al. were the first to report a case of Resonance stent insertion and successful management of ureteral obstruction due to retroperitoneal fibrosis from metastatic breast cancer [109]. The obstruction had not been controlled by the previous insertion of two 6 Fr double-pigtail PSs. The ureter was patent over a 4 month follow-up period. Resonance stent insertion was used to manage malignant ureteral obstruction without bulky pelvic disease in 15 patients (17 ureters) who were followed up for between 1 week and 8 months [110]. In three patients, the initial stent was exchanged after 6 months, and after 12 months in one patient. Long-term drainage of the obstructed ureters was reported to be efficient and encrustation was minimal. Stents were patent and functioning in four patients who were still alive at the end of the follow-up period. The Resonance stents were not removed in seven patients who died during the follow-up period. Nagele et al. treated 14 patients (18 ureters) with ureteral obstruction of either benign ($n$ = 5) or malignant etiology ($n$ = 13) [111]. Mean follow-up was 8.6 months. Encrustation was evident on two stents. Seven stents were removed due to persistent hematuria, severe dysuria, pain, and inadequate drainage. In an attempt to ensure patient comfort, an appropriate stent length should be selected. In addition, satisfactory drainage under circumstances of extrinsic ureteral obstruction was confirmed by an experimental study. Nevertheless, less overall flow than with a standard PS was noted for the Resonance stent [113].

Our group assessed in a porcine model the effect of SWL or radiotherapy on ureters with an indwelling Resonance stent. The histologic deterioration of pig ureters stented with Resonance was not significant compared to control ureters (standard stents) after SWL or radiotherapy, and ureteral temperature was not detected to be significantly higher for the Resonance ureters [114, 115].

The clinical efficiency of Resonance was evaluated by our group in a clinical trial including 50 patients with malignant or benign ureteral obstructions [112]. All cases of extrinsic obstruction due to malignant factors were managed adequately (25 patients), while patency was observed in 44% of the benign intrinsic obstruction cases (25 patients). The benign case group included patients with lithiasis, ureteroileal obstruction, iatrogenic strictures, or an occluded ureteral MS and who were contraindicated for any surgical or endoscopic procedures due to comorbidities. Further clinical trials are deemed necessary to clarify the indications for the insertion of the Resonance stent. Average overall follow-up was 8.5 months (range 4–14 months), and the mean follow-up for malignant and benign cases was 11 months and 6.8 months, respectively. The removed Resonance stents underwent laboratory investigation to identify the presence of encrustation and the type of deposits. Encrustation was evident in 20% of the extracted stents. The most common location of enscrustation was the edges of the stent. Even stents without evident encrustation were observed to have deposits on scanning electron microscopy (Figures 73.1 and 73.2). Calcium oxalate was the most frequent encrustation deposit.

The clinical application of the Resonance stent in ureteroenteric strictures was reported to be unsuccessful by Garg et al., who inserted it for the management of 10 strictures in 10 patients with ileal conduits [116]. Distant migration was observed in nine cases in a mean of

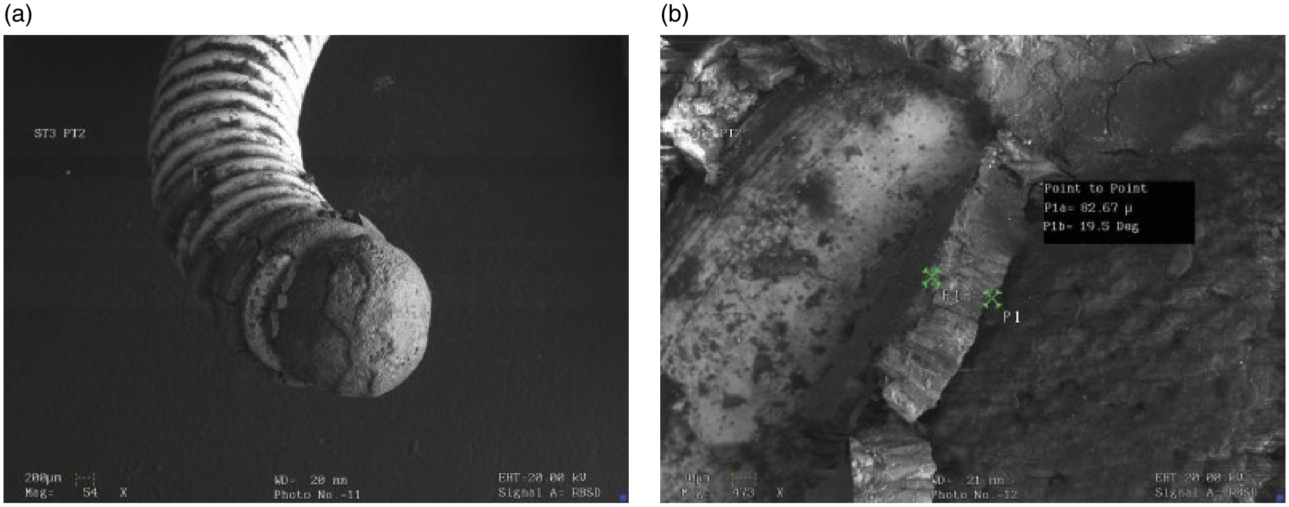

**Figure 73.1** (a) Scanning electron microscopy image obtained from the lower extremity of a Resonance stent that was indwelling for 9 months. Note the encrustation layer, which was barely visible macroscopically. (b) Same Resonance stent at higher magnification. The crystals of the encrustation deposits are visible.

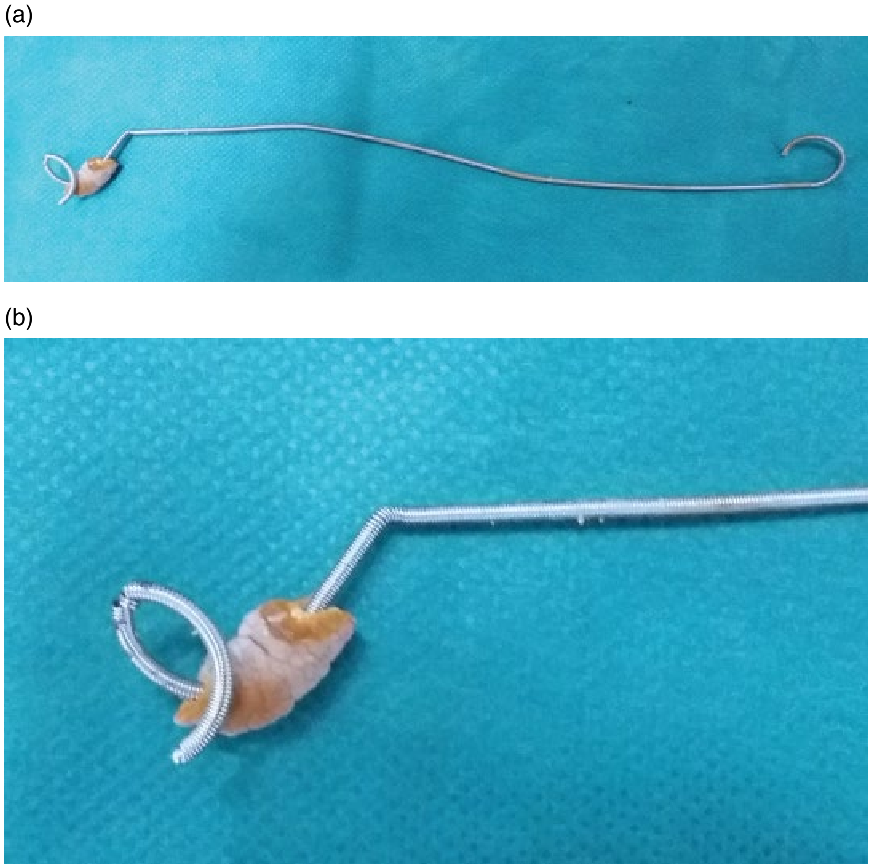

**Figure 73.2** (a) A heavily encrusted Resonance stent with an indwelling time of 12 months. At the exchange of the stent, a large stone burden on the distal coil of the stent was noted. Removal of the stent was impossible and the patient was treated with laser lithotripsy of the stone. Some visible encrustation sites are also present on the stent. (b) The distal coil of the stent with a portion of the initial stone burden on it. Notice that the spiral coil of the stent has been damaged during the laser lithotripsy.

21 days (range 3–60 days). Lopez-Huertas et al. managed 13 patients with benign upper urinary tract ureteral obstructions with the Resonance stent (15 stents) [117]. The majority of the stents provided adequate drainage and 12 patients were efficiently managed. The stents were removed in three patients who showed voiding symptoms such as hematuria. The remaining patients had their stents exchanged after a mean follow-up of 11.6 months. The investigators also conducted a cost-effectiveness analysis and reported a significant cost reduction in favor of the Resonance stent. More recently, Kadlec et al. published their 5-year experience with the Resonance stent [118]. A total of 139 metallic stents were placed in 47 patients, including 27 (57%) with malignant and 20 (43%) with a benign etiology ureteral obstruction. A failure rate of 28% was reported due to pain, stent migration, progressive renal insufficiency, encrustation, recurrent urinary tract infection, progressive hydronephrosis, hematuria, or lower urinary tract symptoms. The failure rates were similar for malignant and benign cases. Nonetheless, Resonance stents were successful in managing benign and malignant ureteral obstruction in the majority of the patients in their series, and a subset of patients in each group continued to do well for more than 3 years' overall follow-up [118]. See Video 73.1 .

### Drug-eluting metal mesh stents

Interventional cardiology has gained significant experience with drug-eluting MSs (DESs). In fact, the DESs represent the most commonly used stents in this specialty. The concept of DESs is to minimize or even eliminate the reaction of the coronary tissue to the stent, which is responsible for platelet adhesion (activation of coagulation cascade) and neointimal hyperplasia [119]. The use of DESs in the ureter is currently limited to experimental animal studies, which have demonstrated reduction of ureteral tissue hyperplasia. Our group has investigated the effect of the paclitaxel-eluting stent in porcine ureters (10 pigs in total). A DES was inserted in one ureter and a bare MS in the other ureter of each animal. Over a follow-up period of 21 days, the majority of MSs were occluded and the remaining MSs were stenosed by hyperplastic reaction, while all the DESs were patent [119]. Later, we evaluated zotarolimus-eluting MSs (Endeavor; Medtronics, Minneapolis, MN, USA) in porcine and rabbit models. Three weeks after placement we observed less hyperplastic reaction in the DESs in comparison to the bare MSs, which were used as the control in the contralateral ureter of the same animals [120] (Figure 73.3). The effectiveness of DESs in these animal models is promising for their clinical application.

## Outcome of long-term ureteral stenting

The long-term use of ureteral stents currently represents a challenge for biomaterial science, pharmacology, and urologic research [1]. The frequent exchange of double-pigtail PSs is accepted clinical practice, with complications addressed by pharmaceutical therapy or additional interventions, and these stents should not be expected to be in place for longer than a few months. Clinical experience with biodegradable PSs remains limited and further refinement is necessary for the wide acceptance of these stents [1]. The development of newer biodegradable materials could lead to the introduction of new biodegradable stents. Drug-eluting and drug-coated PSs are rapidly evolving and their first clinical application appears promising. Moreover, the potential of the latter stent type could be increased with the countless pharmaceutical substances that could be used on their surfaces.

MSs are a completely different category of stent and are used significantly less frequently in urologic practice. Nevertheless, experience has accumulated over the years. Long-term results have proved to be poor despite the initial promising outcome [1, 99]. Thus, patients

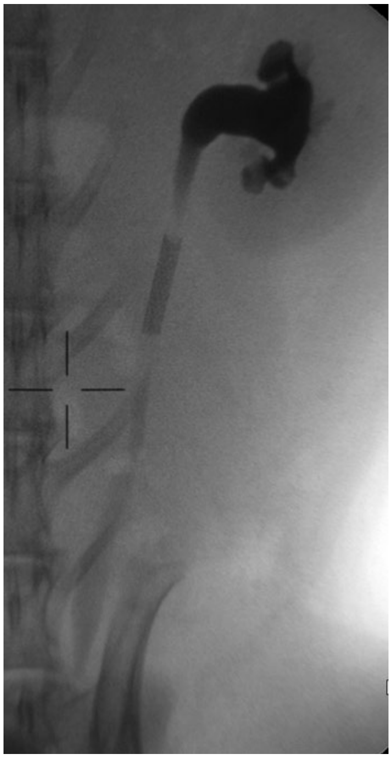

**Figure 73.3** Fluoroscopic image of a zotarolimus metal stent a week after its insertion in a rabbit ureter. Note the trumpet-like configuration on the ureter segment located at the upper extremity of the stent. The configuration did not influence the patency of the stent. Note the lack of hyperplastic reaction in the lumen of the stent.

should be carefully selected for stenting with an MS. The first MS with a double-pigtail design provides adequate drainage in cases of PS failure and has shown excellent results in long-term management of malignant ureteral obstruction. In contrast, benign cases have been associated with unfavorable results. Further clinical investigations will elucidate the true efficacy and indications for these stent [111]. DESs are the next step in the evolution of metal stenting in the ureter. These stents have a tremendous impact in interventional cardiology. Their use to overcome the difficulties encountered during metal stenting is expected. Available experimental reports are rare but still promising regarding the possible outcome in clinical trials.

# Smith's Textbook of Endourology

# Smith's Textbook of Endourology

Fourth Edition

**VOLUME 2**

**Edited by**

*Arthur D. Smith, MD*
*Professor of Urology*
*The Arthur Smith Institute for Urology*
*Zucker School of Medicine at Hofstra/Northwell*
*Lake Success, NY, USA*

*Glenn M. Preminger, MD*
*James F. Glenn Professor of Urology and Chief*
*Division of Urology, Department of Surgery*
*Duke University Medical Center*
*Durham, NC, USA*

*Louis R. Kavoussi, MD*
*Waldbaum Gardner Professor and Chairman*
*The Arthur Smith Institute for Urology*
*Zucker School of Medicine at Hofstra/Northwell*
*Lake Success, NY, USA*

*Gopal H. Badlani, MD, FACS, FRCS (Hon)*
*Vice Chair Urology*
*Professor of Urology and Gynecology*
*Wake Forest University*
*Winston-Salem, NC, USA*

**Assistant Editor**

*Ardeshir R. Rastinehad, DO, FACOS*
*Associate Professor of Urology and Radiology*
*Director of Focal Therapy and Interventional Urologic Oncology*
*Department of Radiology and Urology*
*Icahn School of Medicine at Mount Sinai*
*New York, NY, USA*

**List of Contributors** *xvi*
**Foreword** *xl*
**Preface** *xli*
**About the Companion Website** *xliii*

## VOLUME 1

### SECTION 1 BASIC PRINCIPLES

1 **Care and Sterilization of Instruments** *3*
*Carol Olsen*

2 **Radiation Safety During Diagnosis and Treatment** *14*
*Yasser A. Noureldin & Sero Andonian*

3 **Enhanced Endoscopic Imaging** *38*
*Ghalib A. Jibara & Michael E. Lipkin*

4 **Preoperative Antibiotics and Prevention of Sepsis in Urologic Endoscopic Surgery** *57*
*Manish N. Patel & Jorge Gutierrez-Aceves*

5 **Management of the Anticoagulated Patient** *73*
*Zeph Okeke*

### SECTION 2 PERCUTANEOUS RENAL SURGERY

### Part 1 Perioperative Considerations

6 **Surgical Anatomy of the Kidney for Endourological Procedures** *87*
*Francisco J.B. Sampaio*

7 **Nephrolithometric Scoring Systems for Percutaneous Nephrolithotomy** *108*
*Roshan Patel, Daniel J. Lama, & Zhamshid Okhunov*

8 **Pathophysiology of Urinary Tract Obstruction** *124*
*Frederick A. Gulmi & Diane Felsen*

9 **Organizing the Endourological Operating Room** *143*
*Ravindra B. Sabnis, Abhishek Singh, & Shashikant Mishra*

10 **Endoscopic Training/Simulation** *159*
*Zichen Zhao & Robert M. Sweet*

## Part 2 Patient Positioning for Percutaneous Access

11 **Patient Positioning, the Supine Position, and the Rationale of ECIRS** *173*
*Cesare M. Scoffone & Cecilia M. Cracco*

12 **Prone, Lateral, and Flexed: Patient Positioning for Percutaneous Nephrolithotomy** *185*
*Robert J. Sowerby, A. Andrew Ray, & R. John D'A. Honey*

## Part 3 Imaging for Access

13 **Percutaneous Nephrolithotomy Access Under Fluoroscopic Control** *210*
*Norberto O. Bernardo & Maximiliano Lopez Silva*

14 **Dyna-CT-Guided versus Standard CT-Guided Renal Access** *221*
*Manuel Ritter & Maurice-Stephan Michel*

15 **Endoscopically Guided Percutaneous Renal Access** *229*
*Zhamshid Okhunov, Kamaljot S. Kaler, Simone Vernez, Rahul Dutta, Jaime Landman, & Ralph V. Clayman*

16 **Percutaneous Nephrolithotomy Access Under Ultrasound** *237*
*Mahesh R. Desai & Arvind P. Ganpule*

17 **New Concepts of Renal Access: iPad, GPS, and Others** *244*
*Estevao Lima, Pedro L. Rodrigues, Marie-Claire Rassweiler-Seyfried, & João L. Vilaça*

## Part 4 Selection of Access and Dilation

18 **Percutaneous Nephrolithotomy: Upper Pole Access** *255*
*Davis P. Viprakasit & Nicole L. Miller*

19 **Percutaneous Nephrolithotomy Access Without Image Guidance** *264*
*Arthur D. Smith*

20 **Percutaneous Nephrolithotomy Access: Robotic** *269*
*Michelle Jo Semins, Dan Stoianovici, & Brian R. Matlaga*

21 **Dilation of the Nephrostomy Tract** *275*
*Peter Alken*

## Part 5 Stone Removal

22 **Rigid and Flexible Nephroscopy** *285*
*Timothy Y. Tran & Mantu Gupta*

23 **Percutaneous Antegrade Ureteroscopy** *294*
*Burak Turna, Umit Eskidemir, & Oktay Nazli*

24 **Small-caliber Percutaneous Nephrolithotomy: Mini, UMP, and Micro-Perc** *301*
*Janak D. Desai & Arkadiusz Miernik*

25 **Percutaneous Nephrolithotomy: Special Problems with Staghorns** *310*
*Monica A. Farcas & Kenneth T. Pace*

26 **Percutaneous Nephrolithotomy: Stone Extraction and Lithotripsy** *322*
*Samir Derisavifard & Arthur D. Smith*

27 **Percutaneous Nephrolithotomy in Children** *332*
*Adam S. Howe, Jordan S. Gitlin, & R. John D'A. Honey*

**Part 6 Other Uses of Nephrostomy Access**

28 **Percutaneous Nephrolithotomy of Calyceal Diverticula, Infundibular Stenosis, and Simple Cysts** *341*
*Nadya E. York & James E. Lingeman*

29 **Percutaneous Instillation of Chemolytic, Chemotherapeutic, and Antifungal Agents** *353*
*Mohamed A. Elkoushy, Philippe D. Violette, & Sero Andonian*

30 **Percutaneous Treatment of Ureteropelvic Junction Obstruction** *377*
*Michael W. Sourial, Bodo E. Knudsen, & Paul J. Van Cangh*

31 **Percutaneous Management of Upper Tract Urothelial Carcinoma** *384*
*Shu Pan & Piruz Motamedinia*

**Part 7 Exit Strategy and Complications**

32 **The Access-related Complications of Percutaneous Nephrolithotomy** *390*
*Vinaya Vasudevan, Zeph Okeke, & Arthur D. Smith*

33 **Hemorrhagic Complications Associated with Percutaneous Nephrolithotomy** *397*
*Sriram V. Eleswarapu & David A. Leavitt*

34 **Diagnosis and Management of Thoracic Complications of Percutaneous Renal Surgery** *409*
*John R. Bell & Stephen Y. Nakada*

35 **Bowel and Other Organ Injuries with Percutaneous Nephrolithotomy** *422*
*John J. Knoedler, Matthew T. Gettman, & Chad J. Fleming*

36 **Exit Strategies After Percutaneous Nephrolithotomy** *427*
*Damien M. Bolton & Derek B. Hennessey*

37 **Problems with Residual Stones** *441*
*Noah E. Canvasser & Margaret S. Pearle*

**SECTION 3 URETEROSCOPY**
**Part 1 General Principles**

38 **Ureteral Anatomy** *455*
*Gary Faerber, Amir H. Lebastchi, & Rita P. Jen*

39 **Rigid Ureteroscopes** *465*
*Omar M. Aboumarzouk & Francis X. Keeley, Jr.*

40 **Flexible Ureteroscopes** *475*
*Vincent G. Bird & John M. Shields*

41 **Rigid Ureteroscope with Flexible Tip and Special Instrumentation** *486*
*Yinghao Sun & Xiaofeng Gao*

42 **Digital Ureteroscopes** *497*
*Murat Binbay & Burak Ucpinar*

43 **Ureteroscopy Working Instruments** *506*
*Renato N. Pedro & Manoj Monga*

44 **Access to the Ureter: Rigid Ureteroscopy** *514*
*Jose De La Cerda, III & Timothy Y. Tseng*

45 **Access to the Ureter: Flexible Ureteroscopy** *521*
*Ojas Shah & Mark V. Silva*

46 **Ureteroscopy Energy Sources** *532*
*Daniel A. Wollin & Glenn M. Preminger*

47 **Ureteroscopic Management of Ureteral Calculi** *542*
*Charles U. Nottingham, Melanie A. Adamsky,*
*Richard J. Fantus, & Glenn S. Gerber*

48 **Ureteroscopic Management of Renal Calculi** *549*
*Steeve Doizi & Olivier Traxer*

49 **Diagnostic Ureteroscopy** *562*
*Hendrik Heers & Benjamin W. Turney*

50 **Ureteroscopic Diagnosis and Treatment of Upper Urinary Tract Neoplasms** *568*
*Scott G. Hubosky & Demetrius H. Bagley*

## Part 2 Ureteroscopic Management of Ureteral Obstruction

51 **Retrograde Endopyelotomy** *584*
*Weil R. Lai & Raju Thomas*

52 **Endoscopic Management of Mid-ureteral Obstruction** *592*
*Samuel Abourbih & D. Duane Baldwin*

53 **Endoscopic Management of Distal Ureteral Strictures** *604*
*Michael Zhang, Ali Fathollahi, Joel Hillesohn, & Majid Eshghi*

54 **Endoscopic Management of Ureteroenteric Strictures** *629*
*Thomas Masterson & Robert Marcovich*

55 **Ureterorenoscopy: Ureteral Stents and Postoperative Care** *642*
*Ben H. Chew, Anthony Emmott, Dirk Lange, & Ryan F. Paterson*

56 **Ureteroscopy Complications** *653*
*Joel E. Abbott & Roger L. Sur*

57 **Retrograde Intrarenal Surgery in the Future: Robotics** *668*
*Anup Patel*

## SECTION 4 SHOCK-WAVE LITHOTRIPSY

58 **Physics of Shock-wave Lithotripsy** *691*
*Andreas Neisius & Pei Zhong*

59 **Lithotripsy Systems** *713*
*Geert G. Tailly*

60 **Shock-wave Lithotripsy of Renal Calculi** *731*
*Brian H. Eisner & Naren Nimmagadda*

61 **Shock-wave Lithotripsy of Ureteral Calculi** *745*
*Thomas Tailly & Hassan Razvi*

62 **Complications of Shock-wave Lithotripsy** *756*
*Christian Türk & Aleš Petřík*

## SECTION 5 STONE MANAGEMENT IN UROLOGY

### Part 1 General Principles

63 **Natural History of Stones** *765*
*Johann P. Ingimarsson & Amy E. Krambeck*

64 **Initial Choice of Therapy in the Stone Patient** *777*
*Peter L. Steinberg & David M. Hoenig*

65 **Management of Urolithiasis in Pregnancy** *786*
*Husain Alenezi & John D. Denstedt*

66 **Management of Renal Colic and Triage in the Emergency Department** *798*
*Marius C. Conradie*

### Part 2 Management of Stones in Abnormal Situations

67 **Management of Stones in Horseshoe Kidneys** *811*
*Chandra Shekhar Biyani & Adrian D. Joyce*

68 **Pelvic Kidneys** *818*
*Win Shun Lai, Vidhush K. Yarlagadda, & Dean G. Assimos*

69 **Management of Stone Disease in Renal Transplant Kidneys** *827*
*Brian Duty & Michael Lam*

70 **Stones in Urinary Diversions** *836*
*Bodo E. Knudsen & Michael W. Sourial*

71 **Management of Stones in Obesity** *843*
*Omer L. Tuncay & Cenk Acar*

### Part 3 Cost-effectiveness and Long-term Stenting

72 **Cost-effective Strategies for Stone Management** *853*
*Justin I. Friedlander & Eric M. Ghiraldi*

73 **Long-term Stenting of the Ureter** *864*
*Panagiotis Kallidonis, Wissam Kamal, Dimitrios Kotsiris, Dimitrios Karnabatidis, & Evangelos Liatsikos*

**Index** *i1*

## VOLUME 2

### SECTION 6 LAPAROSCOPY AND ROBOTIC SURGERY

### Part 1 General Principles

74 **New Surgical Robotics** *881*
*Alabdulaali Ibrahim & Koon Ho Rha*

75 **Training and Credentialing Laparoscopic and Robotic Surgery** *887*
*Domenico Veneziano & David M. Hananel*

76 **Patient Preparation and Operating Room Setup for Laparoscopic and Robotic Surgery** *901*
*Weil R. Lai & Benjamin R. Lee*

77 **Patient Preparation and Operating Room Setup for Robotic Surgery** *909*
*Dima Raskolnikov, Mahir Maruf, & Arvin K. George*

78 **Physiologic Considerations in Laparoscopic and Robotic Surgery** *917*
*Adam G. Kaplan & Michael N. Ferrandino*

79 **Anesthetic Management During Laparoscopic/Robotic Surgery** *928*
*Judith Aronsohn, Oonagh Dowling, & Greg Palleschi*

### Part 2 Instrumentation, Access, and Exit

80 **Laparoscopic Surgery: Basic Instrumentation** *944*
*Ornob Roy*

81 **Robotic Surgery: Basic Instrumentation and Troubleshooting** *954*
*Wooju Jeong, Mouafak Tourojman, & Craig G. Rogers*

82 **Minimally Invasive Reconstructive Techniques: Suture, Staple, and Clip Technology** *960*
*Ali Abdel Raheem & Koon Ho Rha*

83 **Transperitoneal Access and Trocar Placement** *973*
*Angelo Territo & Alberto Breda*

84 **Retroperitoneal Access and Trocar Placement** *987*
*Lambros Stamatakis & Soroush Rais-Bahrami*

85 **Basic Hand-assisted Laparoscopic Techniques** *994*
*Sapan N. Ambani & J. Stuart Wolf, Jr.*

86 **Laparoscopic Exit: Specimen Removal, Closure, and Drainage** *1010*
*Fernando J. Kim, Riccardo Autorino, & Rodrigo Donalisio da Silva*

### Part 3 Complications

87 **Complications in Urologic Laparoscopy** *1021*
*David Canes, Camilo Giedelman, & Rene J. Sotelo*

88 **Complications of Laparoscopy Including Robotics** *1032*
*Friedrich-Carl von Rundstedt, Marcelo Chen, & Richard E. Link*

## Part 4 Laparoscopy/Robotics for Malignant Disease

89 **Pelvic Lymphadenectomy** *1048*
*Marc D. Manganiello & Andrew A. Wagner*

90 **Endoscopic Subcutaneous Modified Inguinal Lymph Node Dissection for Squamous Cell Carcinoma of the Penis** *1060*
*Jay T. Bishoff & Kefu Du*

91 **Laparoscopic and Robotic Retroperitoneal Lymph Node Dissection** *1066*
*James R. Porter*

92 **Laparoscopic Radical Nephrectomy** *1077*
*Simpa S. Salami*

93 **Robotic Partial Nephrectomy: Advancements and Innovations** *1088*
*Sameer Chopra, Mehar Bains, & Inderbir S. Gill*

94 **Intraoperative Assessment of Tumor Resection Margins** *1097*
*Ilan Z. Kafka & Timothy D. Averch*

95 **Laparoscopic Radical Nephroureterectomy** *1101*
*Wayland J. Wu & Jessica E. Kreshover*

96 **Laparoscopic and Robotic Radical Cystectomy in Males and Females** *1107*
*Douglas S. Scherr, David M. Golombos, & Abimbola Ayangbesan*

97 **Robot-assisted Laparoscopic Partial Cystectomy** *1115*
*Manish A. Vira & Paras H. Shah*

98 **Laparoscopic Cystoprostatectomy with Intracorporeal Ileal Conduit** *1125*
*Alvin C. Goh, Brian J. Miles, & Arun Rai*

99 **Laparoscopic/Robotic Continent Diversion** *1128*
*Christopher R. Reynolds & Ashok K. Hemal*

100 **Laparoscopic Radical Prostatectomy** *1140*
*Jens Rassweiler, Giovannalberto Pini, Marcel Fiedler, Ali Serdar Goezen, & Dogu Teber*

101 **Robot-assisted Laparoscopic Radical Prostatectomy** *1169*
*Zeyad Schwen & Misop Han*

102 **Optimizing Outcomes During Laparoscopic and Robot-assisted Radical Prostatectomy** *1179*
*Matthew Goland-Van Ryn, Daniel Rosen, Thomas Bessede, & Ashutosh Tewari*

## Part 5 Laparoscopy/Robotics for Benign Disease

103 **Laparoscopic and Robotic Reconstructive Ureteral Surgery: Basic Principles** *1194*
*Aaron C. Weinberg, Yuka Yamaguchi, Lee C. Zhao, & Michael D. Stifelman*

104 **Laparoscopic Applications to Renal Calculus Disease** *1208*
*Christopher S. Han & Sammy E. Elsamra*

105 **Laparoscopic Treatment of Renal Cysts and Diverticula** *1221*
*Salvatore Micali, Eugenio Martorana, Giacomo Maria Pirola, & Giampaolo Bianchi*

106 **Laparoscopic and Robotic Techniques for Management of Pelvic Organ Prolapse** *1234*
*Sandeep Gurram & Farzeen Firoozi*

107 **Laparoscopic and Robotic Techniques for Repair of Female Genitourinary Fistulas** *1242*
*Chad Baxter & Vishnukamal Golla*

108 **Laparoscopic, Laparoendoscopic Single-site, and Robot-assisted Living Donor Nephrectomy** *1250*
*Ganesh Sivarajan & Ravi Munver*

109 **Robotic Kidney Transplantation** *1259*
*Rajesh Ahlawat, Sohrab Arora, & Mani Menon*

110 **Minimally Invasive Surgery for Benign Prostate Disease: Laparoscopic and Robotic Techniques** *1269*
*Mark Ferretti, Amul Bhalodi, & John Phillips*

111 **Laparoscopic Adrenalectomy** *1278*
*Tadashi Matsuda, Hidefumi Kinoshita, Yoshihide Kawasaki, & Akira Miyajima*

112 **Laparoscopic and Robotic Surgery of the Seminal Vesicles** *1292*
*Eric H. Kim, R. Sherburne Figenshau, & Gerald L. Andriole*

113 **Modern Techniques in Abdominal Wall Hernia Repair: a Guide for the Practicing Endourologist** *1299*
*Douglas K. Held*

114 **Robot-assisted Vasectomy Reversal** *1313*
*Parviz K. Kavoussi*

## Part 6 Laparoscopy/Robotics in Children

115 **Laparoscopic Considerations in Children** *1323*
*Rajeev Chaudhry, Michelle Yu, & Michael C. Ost*

116 **Laparoscopic and Robotic Pyeloplasty in Children** *1328*
*Kai-wen Chuang*

117 **Lower Ureteral Reconstruction: Robotic Surgery** *1335*
*S. Duke Herrell*

118 **Laparoscopic Management of the Undescended Testicle** *1344*
*Brian A. VanderBrink*

119 **Laparoscopic Varicocelectomy** *1353*
*Bradley A. Morganstern & Lane S. Palmer*

## Part 7 Laparoscopy and Robotics: LESS and NOTES

120 **Laparoendoscopic Single-site Surgery: Ports, Access, and Instrumentation** *1361*
*Noah E. Canvasser & Jeffrey A. Cadeddu*

121 **Laparoendoscopic Single-site Upper Tract Surgery** *1373*
*Christian Tabib, Geoffrey Gaunay, & Lee Richstone*

122 **Robotic Laparoendoscopic Single-site Lower Tract Surgery** *1385*
*Daniel Ramirez, Matthew J. Maurice, & Jihad H. Kaouk*

## SECTION 7 IMAGE-GUIDED DIAGNOSTICS AND THERAPEUTICS

### Part 1 Upper Tract

123 **Diagnosis of Renal Masses: Radiological** *1393*
*Gail S. Smith, Carolyn K. Donaldson, & Richard M. Gore*

124 **Renal Mass Biopsy** *1425*
*M. Pilar Laguna & Jean de la Rosette*

125 **Radiofrequency Ablation of Renal Tumors** *1442*
*Ryan L. Steinberg & Chad R. Tracy*

126 **Percutaneous Cryoablation of Renal Masses** *1454*
*David N. Siegel & Alok A. Anand*

### Part 2 Angio-embolization in Urology

127 **Gonadal Vein Embolization** *1464*
*Pratik A. Shukla, Gajan Sivananthan, & Ardeshir R. Rastinehad*

128 **Renal Angiography and Embolization** *1479*
*Igor Lobko & Anthony D. Mohabir*

129 **Selective Arterial Prostate Embolization** *1488*
*Robert C. Blue, Aaron M. Fischman, & Ardeshir R. Rastinehad*

### Part 3 Focal Therapy Lower Tract

130 **The Role and Methodology of Multiparametric MRI and Fusion-guided Biopsy in the Management of Prostate Cancer Patients** *1495*
*Raju R. Chelluri, Arvin K. George, Joseph A. Baiocco, Baris Turkbey, & Peter A. Pinto*

131 **Focal Therapy of Prostate Cancer** *1509*
*Kae Jack Tay & Thomas J. Polascik*

132 **Focal Laser Ablation for Carcinoma of Prostate** *1523*
*Tonye A. Jones, Shyam Natarajan, & Leonard S. Marks*

133 **Image-guided Prostate Brachytherapy** *1534*
*Michael R. Folkert, Neil B. Desai, & Yoshiya Yamada*

134 **Image-guided External Beam Radiotherapy** *1550*
*Brett Cox, Lucille Lee, & Louis Potters*

135 **High-intensity Focused Ultrasound of the Prostate** *1567*
*Edward J. Bass, Mark Emberton, & Hashim U. Ahmed*

136 **Cryotherapy of the Prostate** *1580*
*Daniel B. Rukstalis*

137 **Cryosurgical Ablation of the Prostate** *1589*
*Rajan Ramanathan, Yaw A. Nyame, & J. Stephen Jones*

138 **Contrast-enhanced Ultrasound in Urology** *1605*
*Rogier R. Wildeboer, Jean de la Rosette, Massimo Mischi, & Hessel Wijkstra*

139 **Principles of Prostate Magnetic Resonance Imaging** *1616*
*Sonia Gaur, Baris Turkbey, & Peter L. Choyke*

140 **Male Lower Urinary Tract Symptoms and Assessment** *1627*
*Henry Tran, Matthew P. Rutman, Doreen E. Chung, & Jerry G. Blaivas*

141 **Office-based Cystoscopy: Continued Advances** *1643*
*Judson D. Davies & Sam S. Chang*

142 **Equipment Setup and Patient Handouts** *1649*
*John R. Schwabe, Amanda P. Hughes, Crystal R. Combs, & Gopal H. Badlani*

143 **Local Anesthesia for Minimally Invasive Treatment of the Prostate in the Office Setting** *1661*
*Arun Rai & Ricardo R. Gonzalez*

144 **Laser in Benign Prostatic Hyperplasia Treatment: Basic Principles** *1672*
*Christopher Netsch, Bilal Chughtai, Alexis E. Te, Ahmed M. Elshal, Mostafa M. Elhilali, & Andreas J. Gross*

145 **Holmium Laser Therapy of the Prostate** *1681*
*Ahmed M. Elshal & Mostafa M. Elhilali*

146 **532 nm High-power Transurethral Laser Prostatectomy** *1693*
*Bilal Chughtai, Dominique Thomas, & Alexis E. Te*

147 **Thulium Lasers** *1707*
*Andreas J. Gross & Christopher Netsch*

148 **The Prostatic Urethral Lift Procedure Using UroLift Implants: Novel, Minimally Invasive Therapy for Benign Prostatic Hyperplasia** *1719*
*Daniel B. Rukstalis*

149 **Goals and Expectations of Ablation Techniques and Emerging Therapies for Benign Prostatic Hyperplasia: An Editorial** *1727*
*Catriona I. MacRae & Peter J. Gilling*

150 **Monopolar Transurethral Resection of Prostate** *1733*
*Madhu S. Agrawal & Dilip K. Mishra*

151 **Ablation of Prostate: Bipolar Resection** *1743*
*Jaspreet S. Sandhu*

152 **Bipolar Vaporization of the Prostate** *1752*
*Ahmet Karakeci, Kyle Richards, & Gopal H. Badlani*

153 **Single Port for Prostate Surgery** *1762*
*Rene J. Sotelo, Oscar D. Martín Garzón, Camilo Giedelman, Fatima Z. Husain, & Mihir Desai*

**154** **Bladder Injections for Refractory Overactive Bladder: Intra- and Transvesical Procedures** *1775*
*Adam Althaus & Anurag K. Das*

**155** **STING Procedure for Reflux** *1784*
*Steve J. Hodges*

**156** **Minimally Invasive Therapy for Bladder Pain Syndrome (Interstitial Cystitis)** *1792*
*Ricardo Palmerola, Sandeep Gurram, & Robert Moldwin*

**157** **New Techniques for Resecting Bladder Tumors** *1806*
*Alexey G. Martov, Dmitry V. Ergakov, Nikolay A. Baykov, & Zhamshid Okhunov*

**158** **Incision: Endoscopic Management of Urethral Stenoses** *1815*
*Gerald H. Jordan & Kurt A. McCammon*

**159** **Endoscopic Management of Bladder Neck Contracture Following Radical Prostatectomy** *1826*
*Susan MacDonald, R. Caleb Kovell, Joseph Tortora, & Ryan P. Terlecki*

**160** **Single-incision Slings** *1832*
*Michael J. Kennelly & Dina A. Bastawros*

**161** **Bioinjectables for Stress Urinary Incontinence** *1847*
*Ryan Dobbs, Simone Crivellaro, & John J. Smith III*

**162** **Midurethral Slings for the Treatment of Female Stress Urinary Incontinence** *1854*
*Alice Drain & Victor W. Nitti*

**163** **Maxi/Pubovaginal Sling** *1871*
*Gopal H. Badlani & Joao P. Zambon*

**164** **Mesh Complications Associated with Vaginal Prolapse Surgery** *1880*
*Jeffrey S. Schachar & G. Willy Davila*

**165** **Male Slings for Treatment of Post-prostatectomy Incontinence** *1890*
*Ajay K. Singla & Nirmish Singla*

**166** **Neuromodulation** *1902*
*Dayron Rodríguez & Anurag K. Das*

**Index** *i1*

# List of Contributors

***Joel E. Abbott, DO***
Associate Director
Advanced Kidney Stone Center of the Americas
Chesapeake Urology
University of Maryland School of Medicine
Hanover, MD, USA

***Omar M. Aboumarzouk, MBChB, MSc, PhD, MRCS(Glasg), FRCS(Urol)***
Consultant Urological Surgeon
Department of Urology
Glasgow Urological Research Unit
Queen Elizabeth University Hospital
Glasgow, UK

***Samuel Abourbih, MDCM***
Assistant Professor of Urology
Loma Linda University Medical Center
Loma Linda, CA, USA

***Cenk Acar, MD***
Associate Professor
Eryaman Hospital
Department of Urology
Ankara, Turkey

***Melanie A. Adamsky, MD***
Urology Resident
Section of Urology
Department of Surgery
University of Chicago Medicine
Chicago, IL, USA

***Madhu S. Agrawal, MBBS, MS, MCh, MNAMS***
Head
Department of Urology & Center for Minimally Invasive Endourology
Global Rainbow Healthcare
Agra, India

***Rajesh Ahlawat, MS, MCh***
Chairman
Medanta Kidney and Urology Institute
Gurgaon, India

***Hashim U. Ahmed, FRCS(Urol), PhD, BM, BCh, MA***
Chair of Urology & Consultant Urological Surgeon
Division of Surgery
Department of Surgery and Cancer
Faculty of Medicine
Imperial College London;
Imperial Urology
Imperial College Healthcare NHS Trust
London, UK

***Husain Alenezi, MD***
Consultant Urologist
Urology Unit
Department of Surgery
Sabah Al-Ahmad Urology Center and Al-Adan Hospital
Kuwait

***Peter Alken, MD, PhD***
Professor of Urology
Consultant Urologist
Department of Urology
University Clinic Mannheim
Mannheim, Germany

***Adam Althaus, MD***
Resident in Urology
Harvard Longwood Program in Urology
Boston, MA, USA

***Sapan N. Ambani, MD***
Assistant Professor
Department of Urology
University of Michigan Health Systems
Ann Arbor, MI, USA

***Alok A. Anand, MD, DABR, CIIP***
Interventional Radiologist
Chairman and Chief Quality Officer
Department of Radiology – Eastern Connecticut Health Network
Manchester, CT, USA

**Sero Andonian, MD, MSc, FRCSC, FACS**
Associate Professor
Division of Urology
McGill University Health Centre
McGill University
Montreal, QC, Canada

**Gerald L. Andriole, MD**
Division of Urologic Surgery
Washington University School of Medicine
St. Louis, MO, USA

**Judith Aronsohn, MD**
Assistant Professor
Department of Anesthesiology
Zucker School of Medicine at Hofstra/Northwell
New York, NY, USA

**Sohrab Arora, MS, MCh**
Senior Fellow – Robotic Surgery
Vattikuti Urology Institute
Detroit, MI, USA

**Dean G. Assimos, MD**
Anton Bueschen Chairman
Professor of Urology
Department of Urology
University of Alabama at Birmingham
Birmingham, AL, USA

**Riccardo Autorino, MD**
Attending Urologist and Associate Professor of Urology
Division of Urology
McGuire VAMC and
Virginia Commonwealth University
Richmond, VA, USA

**Abimbola Ayangbesan, BA**
Urology Resident
Vanderbilt University Medical Center
Nashville, TN, USA

**Timothy D. Averch, MD, FACS**
Professor
Vice Chair for Quality
Director of Endourology
Division Chief of Urology – UPMC Presbyterian
Department of Urology
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

**Gopal H. Badlani, MD, FACS, FRCS (Hon)**
Vice Chair Urology
Professor of Urology and Gynecology
Wake Forest University
Winston-Salem, NC, USA

**Demetrius H. Bagley, MD**
The Nathan Lewis Hatfield
Professor of Urology
Professor of Radiology
Department of Urology
Sidney Kimmel Medical College at
Thomas Jefferson University Hospital
Philadelphia, PA, USA

**Mehar Bains**
Research Intern
USC Institute of Urology
Keck School of Medicine
University of South California
Los Angeles, CA, USA

**Joseph A. Baiocco, BS**
Medical Research Scholar
Urologic Oncology Branch
National Cancer Institute
National Institutes of Health
Bethesda;
Medical Student
Sidney Kimme Medical College
Thomas Jefferson University
Philadelphia, PA, USA

**D. Duane Baldwin, MD**
Professor of Urology
Director of Urologic Research
Loma Linda University Medical Center
Loma Linda, CA, USA

**Edward J. Bass, MBChB (Hons)**
Urology Specialist Registrar
The Division of Surgery and
Interventional Science
University College London
London;
Department of Urology
University College London Hospitals
London, UK

**Dina A. Bastawros, MD**
Fellow
Department of Obstetrics and Gynecology
Female Pelvic Medicine and
Reconstructive Surgery
Atrium Health
Charlotte, NC, USA

**Chad Baxter, MD**
Assistant Professor of Urology
David Geffen School of Medicine at UCLA
Los Angeles, CA, USA

**Nikolay A. Baykov, MD**
Doctor of Urology
Department of Urology
Municipal Hospital No. 57
Moscow, Russia

**John R. Bell, MD**
Assistant Professor
Department of Urology
University of Kentucky
Lexington, KY, USA

**Norberto O. Bernardo, MD**
Professor of Urology
Chief, Endourology
Hospital de Clínicas José de San Martín
Universidad de Buenos Aires
Buenos Aires, Argentina

**Thomas Bessede, MD**
Assistant Professor
Department of Urology
University of Paris-Sud
Orsay, France

**Amul Bhalodi, MD**
Chief Resident
New York Medical College
Department of Urology
Valhalla, NY, USA

**Giampaolo Bianchi, MD**
Full Professor of Urology
Department of Urology
University of Modena and Reggio Emilia
Modena, Italy

**Murat Binbay, MD**
Associate Professor of Urology
Chairman of Urology Department
Department of Urology
Haseki Training and Research Hospital
Istanbul, Turkey

**Vincent G. Bird, MD**
Professor of Urology
Department of Urology
University of Florida
Gainesville, FL, USA

**Jay T. Bishoff, MD**
Director
Intermountain Urological Institute
Intermountain Health Care
Salt Lake City, UT, USA

**Chandra Shekhar Biyani, MS, D Urol, FRCS (Urol), FEBU, MSc**
Consultant in Urology
Department of Urology
St James' University Hospital
Leeds, UK

**Jerry G. Blaivas, MD**
Professor of Urology
Department of Urology
Icahn School of Medicine at Mount Sinai
New York, NY, USA

**Robert C. Blue, MD**
Assistant Professor of Radiology
Department of Radiology
Icahn School of Medicine at Mount Sinai
New York, NY, USA

**Damien M. Bolton, MD, MBBS, BA, FRACS, FRCS**
Professor
Department of Urology
Austin Hospital
Heidelberg;
Olivia Newton-John Cancer Wellness and
Research Institute
Heidelberg, VIC, Australia

**Alberto Breda, MD**
Chief
Uro-Oncology Division and Kidney Transplant Units
Fundació Puigvert
Autonoma University of Barcelona
Barcelona, Spain

**Jeffrey A. Cadeddu, MD**
Professor
Ralph C. Smith, MD, Distinguished Chair in Minimally
Invasive Urologic Surgery
Department of Urology
University of Texas Southwestern Medical Center
Dallas, TX, USA

**David Canes, MD**
Associate Professor of Urology
Tufts University Medical Center;
Institute of Urology
Lahey Hospital & Medical Center
Burlington, MA, USA

**Noah E. Canvasser, MD**
Assistant Instructor
Department of Urology
University of Texas Southwestern
Medical Center
Dallas, TX, USA

**Sam S. Chang, MD, MBA**
Patricia and Rodes Hart Endowed Chair of Urologic Surgery
Professor of Urologic Surgery and Oncology
Department of Urological Surgery
Vanderbilt University Medical Center
Nashville, TN, USA

**Rajeev Chaudhry, MD**
Pediatric Urology Fellow
Children's Hospital of Pittsburgh of UPMC
Pittsburgh, PA, USA

**Raju R. Chelluri, MD, MS**
Urology Resident
Division of Urology
Department of Surgery
University of Pennsylvania
Perelman School of Medicine;
Research Fellow
Urologic Oncology Branch
National Cancer Institute
National Institute of Health
Bethesda, MD, USA

**Marcelo Chen, MD, PhD**
Senior Attending Urologist
Department of Urology
MacKay Memorial Hospital;
Associate Professor
Department of Medicine
MacKay Medical College
Taipei, Taiwan

**Ben H. Chew, MD, MSc, FRCSC**
Associate Professor
Department of Urologic Sciences
University of British Columbia
Vancouver, BC, Canada

**Sameer Chopra, MD, MS**
Resident Physician
USC Institute of Urology
Keck School of Medicine
University of South California
Los Angeles, CA, USA

**Peter L. Choyke, MD**
Program Director
Molecular Imaging Program
National Cancer Institute
National Institutes of Health
Bethesda, MD, USA

**Kai-wen Chuang, MD**
CHOC Children's Urology
Pediatric Urologist
HS Assistant Clinical Professor
Department of Urology
University of California
Irvine, CA, USA

**Bilal Chughtai, MD**
Assistant Professor of Urology
Department of Urology
Weill Cornell Medical College
New York Presbyterian Hospital
New York, NY, USA

**Doreen E. Chung, MD, FRCSC**
Assistant Professor
Department of Urology
Female Pelvic Medicine & Reconstructive Surgery
Columbia University
New York, NY, USA

**Ralph V. Clayman, MD**
Professor of Urology
Department of Urology
University of California
Irvine, CA;
Dean Emeritus
University of California Irvine
School of Medicine
Orange, CA, USA

**Crystal R. Combs, RN, CNOR**
Clinical Education Resource Nurse - Robotics Wake Forest Baptist Health
Wake Forest University Baptist Medical Center
Winston-Salem, NC, USA

**Marius C. Conradie, MD**
Urologist in Private Practice
President Southern African Endourology Society
Netcare Waterfall City Hospital
Johannesburg, South Africa

**Brett Cox, MD**
Interim Chair
Department of Radiation Medicine
Lenox Hill Hospital;
Chief of Brachytherapy
Northwell Health;
Co-Director
GU Center of Excellence
Northwell Cancer Institute;
Associate Professor of Radiation Medicine

Zucker School of Medicine at Hofstra/Northwell
Department of Radiation Medicine
Northwell Health
New Hyde Park, NY, USA

***Cecilia M. Cracco, MD, PhD***
Urologist
Department of Urology
Cottolengo Hospital
Torino, Italy

***Simone Crivellaro, MD***
Assistant Professor of Urology
Department of Urology
University of Illinois at Chicago
Chicago, IL, USA

***Anurag K. Das, MD, FACS***
Director
Center for Neuro-urology and Continence
Division of Urology
Department of Surgery
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, MA, USA

***Judson D. Davies, MD***
Clinical Assistant Professor of Surgery
Department of Urological Surgery
Vanderbilt University Medical Center
Nashville, TN, USA

***G. Willy Davila, MD***
Chairman
Department of Gynecology
Section of Urogynecology and Reconstructive
Pelvic Surgery
Cleveland Clinic Florida
Weston, FL, USA

***Jose De La Cerda III, MD, MPH***
Urology Resident
Department of Urology
University of Texas Health Science
Center at San Antonio
San Antonio, TX, USA

***Jean de la Rosette, MD, PhD***
Chairman
Professor of Urology
Department of Urology
Istanbul Medipol University
Istanbul, Turkey

***John D. Denstedt, MD, FRCSC, FACS, FCAHS***
Professor of Urology
Division of Urology
Department of Surgery
Schulich School of Medicine & Dentistry
The University of Western Ontario
London, ON, Canada

***Samir Derisavifard, MD***
Resident in Urology
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

***Janak D. Desai, MS, MCh***
Chief of Urology Services
Samved Hospital and Sterling Hospitals
Ahmedabad, India

***Mahesh R. Desai, MS, FRCS, FRCS, FACS***
Medical Director
Muljibhai Patel Urological Hospital
Nadiad, Gujarat, India

***Mihir Desai, MD***
USC Institute of Urology
Keck School of Medicine
University of Southern California
Los Angeles, CA, USA

***Neil B. Desai, MD, MHS***
Assistant Professor
Department of Radiation Oncology
University of Texas Southwestern Medical Center
Dallas, TX, USA

***Ryan Dobbs, MD***
Urology Resident
Department of Urology
University of Illinois at Chicago
Chicago, IL, USA

***Steeve Doizi, MD, MSc***
Assistant Professor
Sorbonne Université
Department of Urology
GRC n°20
Groupe de Recherche Clinique sur la Lithiase Urinaire
Hôpital Tenon
Paris, France

***Carolyn K. Donaldson, MD***
Associate Professor
Department of Radiology
NorthShore University Health System

University of Chicago
Pritzker School of Medicine
Evanston, IL, USA

***Rodrigo Donalisio da Silva, MD***
Assistant Professor of Surgery/Urology
University of Colorado Denver
Denver Health Medical Center
Denver, CO, USA

***Oonagh Dowling, PhD***
Assistant Professor
Department of Anesthesiology
Zucker School of Medicine at Hofstra/Northwell
New York, NY, USA

***Alice Drain, MD***
Department of Urology
New York University Langone Medical Center
New York, NY, USA

***Kefu Du, MD***
Endourology Fellow
Division of Urologic Surgery
Washington University School of Medicine
St. Louis, MO, USA

***Rahul Dutta, MD***
Resident Physician
Department of Urology
University of California
Irvine, CA, USA

***Brian Duty, MD***
Associate Professor
Department of Urology
Oregon Health and Science University
Portland, OR, USA

***Brian H. Eisner, MD***
Assistant Professor
Department of Urology
Massachusetts General Hospital
Boston, MA, USA

***Sriram V. Eleswarapu, MD, PhD***
Chief Urology Resident
Vattikuti Urology Institute
Henry Ford Health System
Detroit, MI, USA

***Mostafa M. Elhilali, MD (Deceased)***
Division of Urology
McGill University
Montreal, QC, Canada

***Mohamed A. Elkoushy, MD, MSc(Urol), PhD(Urol)***
Professor of Urology
Department of Urology
Suez Canal University
Ismailia, Egypt

***Sammy E. Elsamra, MD***
Assistant Professor
Division of Urology
Rutgers Robert Wood Johnson Medical School
New Brunswick, NJ, USA

***Ahmed M. Elshal, MD***
Urology and Nephrology Center
Mansoura University
Egypt

***Mark Emberton***
The Division of Surgery and Interventional Science
University College London;
Department of Urology
University College London Hospitals
London, UK

***Anthony Emmott, BSc, MD***
Department of Urologic Sciences
University of British Columbia
Vancouver, BC, Canada

***Dmitry V. Ergakov, MD, PhD***
Associate Professor
Department of Urology
Municipal Hospital No. 57
FMBA State Institute of Continuous Medical Education
Moscow, Russia

***Majid Eshghi, MD, FACS, MBA***
Professor of Urology
Department of Urology
Westchester Medical Center Health System
New York Medical College
Valhalla, NY, USA

***Umit Eskidemir, MD, FEBU***
Urologist
Department of Urology
School of Medicine
Ege University
İzmir, Turkey

**Gary Faerber, MD**
Professor
Division of Urology
University of Utah School of Medicine
Salt Lake City, UT, USA

**Richard J. Fantus, MD**
Resident Physician
Section of Urology
Department of Surgery
University of Chicago Medicine
Chicago, IL, USA

**Monica A. Farcas, MEng, MD, FRCSC**
Assistant Professor
Department of Surgery
Division of Urology
St. Michael's Hospital
Toronto, ON, Canada

**Ali Fathollahi, MD**
Fellow
Department of Urology
New York Medical College
New York, NY, USA

**Diane Felsen, PhD**
Associate Professor of Pharmacology Research in Urology (Retired)
Weill Cornell Medicine
New York, NY, USA

**Michael N. Ferrandino, MD**
Associate Professor of Urology
Director, Minimally Invasive Urologic Surgery
Division of Urologic Surgery
Duke University Medical Center
Durham, NC, USA

**Mark Ferretti, MD**
Resident
New York Medical College
Department of Urology
Valhalla, NY, USA

**Marcel Fiedler, MD**
Consultant and Senior Registrar
Department of Urology
SLK Kliniken Heilbronn
University of Heidelberg
Heidelberg, Germany

**R. Sherburne Figenshau, MD**
Chair, Minimally Invasive Urology
Division of Urologic Surgery
Washington University School of Medicine
St. Louis, MO, USA

**Farzeen Firoozi, MD, FACS**
Director FPMRS
Associate Professor of Urology
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

**Aaron M. Fischman, MD, FSIR, FCIRSE**
Associate Professor of Radiology and Surgery
Department of Radiology
Icahn School of Medicine at Mount Sinai
Department of Radiology
New York, NY, USA

**Chad J. Fleming, MD**
Assistant Professor of Radiology
Mayo Clinic
Department of Radiology
Rochester, MN, USA

**Michael R. Folkert, MD, PhD**
Assistant Professor
Residency Program Director
Department of Radiation Oncology
University of Texas Southwestern Medical Center
Dallas, TX, USA

**Justin I. Friedlander, MD**
Assistant Professor of Urology
Director of Endourology
Department of Urology
Einstein Healthcare Network;
Fox Chase Cancer Center
Philadelphia, PA, USA

**Arvind P. Ganpule, MS(General Surgery), DNB(Urology), MNAMS(New Delhi)**
Vice Chairman
Department of Urology
Muljibhai Patel Urological Hospital
Nadiad, Gujarat, India

**Xiaofeng Gao, MD**
Secretary, Urolithiasis Group
Deputy Director of the Department of Urology
Chinese Urological Association
Shanghai, China

**Oscar D. Martín Garzón**
Clínica Cooperativa de Colombia
Universidad Cooperativa de Colombia – Facultad de Medicina
Villavicencio, Colombia

**Geoffrey S. Gaunay, MD**
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

**Sonia Gaur, BS**
Research Fellow
Molecular Imaging Program
National Cancer Institute
National Institutes of Health
Bethesda, MD, USA

**Arvin K. George, MD**
Assistant Professor
Urologic Oncology Branch
National Cancer Institute
National Institute of Health
Bethesda, MD;
Department of Urology
Division of Urologic Oncology
University of Michigan
Ann Arbor, MI, USA

**Glenn S. Gerber, MD**
Professor
Section of Urology
Department of Surgery
University of Chicago Medicine
Chicago, IL, USA

**Matthew T. Gettman, MD**
Erivan Haub Family Endowed
Professor of Urology
Mayo Clinic
Department of Urology
Rochester, MN, USA

**Eric M. Ghiraldi, DO**
Urology Resident
Department of Urology
Einstein Healthcare Network
Philadelphia, PA, USA

**Camilo Giedelman, MD**
Urologic Minimally Invasive Surgeon
Clínica Marly and Fundación Universitaria
Ciencia de la Salud
Hospital de San Jose
Bogotá, Colombia

**Inderbir S. Gill, MD**
USC Institute of Urology
Keck School of Medicine
University of South California
Los Angeles, CA, USA

**Peter J. Gilling, MD, FRACS**
Urologist
Professor of Surgery
University of Auckland
Bay of Plenty Clinical School
Tauranga, New Zealand

**Jordan S. Gitlin, MD**
Assistant Clinical Professor
Department of Pediatric Urology
Cohen Children's Medical Center
Zucker School of Medicine at Hofstra/Northwell
Long Island, NY, USA

**Ali Serdar Goezen, MD**
Vice-chairman
Department of Urology
SLK Kliniken Heilbronn,
University of Heidelberg
Heidelberg, Germany

**Alvin C. Goh, MD**
Director of Advanced Laparoscopic and Robotic
Urology Surgery Programs
Methodist Institute for Technology,
Innovation, and Education;
Assistant Professor of Urology
Weill Cornell Medical College
Department of Urology
Houston Methodist Hospital
Houston, TX, USA

**Matthew Goland-Van Ryn, MD**
Chief Resident, Urology
Department of Urology
Icahn School of Medicine at Mount Sinai
New York, NY, USA

**Vishnukamal Golla, MD, MPH**
Urology Resident
Department of Urology
University of California
Los Angeles, CA, USA

**David M. Golombos, MD**
Assistant Clinical Professor
Department of Urology
Stony Brook School of Medicine
Stony Brook, NY, USA

**Ricardo R. Gonzalez, MD**
Director, Center for Voiding Dysfunction
Houston Methodist Hospital
Houston, TX, USA

**Richard M. Gore, MD**
Professor of Radiology
Department of Radiology
NorthShore University Health System
University of Chicago
Pritzker School of Medicine
Evanston, IL, USA

**Andreas J. Gross, MD**
Head of Department
Department of Urology
Asklepios Klinik Barmbek
Hamburg, Germany

**Frederick A. Gulmi, MD**
Vice Chairman
Department of Urology
Clinical Associate Professor of Urology
NYU School of Medicine
New York;
Chief of Urology
NYU Langone Hospital-Brooklyn
Brooklyn, NY, USA

**Mantu Gupta, MD**
Chair of Urology
Mount Sinai West
New York;
Professor
Icahn School of Medicine at Mount Sinai
New York;
Director of Endourology
Mount Sinai Health Care System
New York;
Director
Mount Sinai Kidney Stone Center
New York, NY, USA

**Sandeep Gurram, MD**
Resident Physician
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
New Hyde Park, NY, USA

**Jorge Gutierrez-Aceves, MD**
Professor of Urology
Director of Endourology
Wake Forest University School of Medicine
Department of Urology
Winston-Salem, NC, USA

**Christopher S. Han, MD**
Urology Resident
Division of Urology
Rutgers Robert Wood Johnson Medical School
New Brunswick, NJ, USA

**Misop Han, MD, MS**
David Hall McConnell Professor in Urology and Oncology
James Buchanan Brady Urological Institute
Johns Hopkins School of Medicine
Baltimore, MD, USA

**David M. Hananel, BSc, BA**
Director
Center for Research in Education & Simulation Technologies
University of Washington
School of Medicine
Seattle, WA, USA

**Hendrik Heers, Dr. med**
Senior Endourology Fellow (EBU)
Department of Urology
Nuffield Department of Surgical Sciences
University of Oxford
Oxford, UK

**Douglas K. Held, MD, FACS**
Northwell Health Long Island Jewish Medical Centre
New Hyde Park, NY, USA

**Ashok K. Hemal, MD, MCh, FACS, FRCS**
Professor
Wake Forest Institute for Regenerative Medicine;
Chair, Robotics Committee
Baptist Medical Center;
Fellowship Director
Robotics and Minimally Invasive Surgery;
Fellowship Co-Director
Endourology
Wake Forest Baptist Medical Center and Wake Forest School of Medicine
Winston-Salem, NC, USA

**Derek B. Hennessey, MD, MBBChBAO, BMedSci, DHSM, PDipHS, FRCSI, FEBU**
Fellow
Department of Urology
Austin Hospital
Heidelberg
Olivia Newton-John Cancer Wellness and Research Institute
Heidelberg, VIC, Australia

**S. Duke Herrell, MD, FACS**
Professor of Urologic Surgery, Biomedical and Mechanical Engineering
Vanderbilt University Medical Center
Nashville, TN, USA

**Joel Hillesohn, MD**
Chief Resident
Department of Urology
New York Medical College
New York, NY, USA

**Steve J. Hodges, MD**
Assistant Professor of Pediatric Urology
Pediatric Urology
Institute for Regenerative Medicine
Wake Forest University School of Medicine
Winston-Salem, NC, USA

**David M. Hoenig, MD**
Chief of Urology
Professor
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

**R. John D'A. Honey, MA, MB, BChir, FRCS(Eng), FRCSC**
Professor of Surgery
Division of Urology
St. Michael's Hospital
Toronto;
Department of Surgery
University of Toronto
Toronto, ON, Canada

**Adam S. Howe, MD**
Pediatric Urology Fellow
Department of Pediatric Urology
Cohen Children's Medical Center
Zucker School of Medicine at Hofstra/Northwell
Long Island, NY, USA

**Scott G. Hubosky, MD**
The Demetrius H. Bagley, Jr. M.D.
Associate Professor of Urology
Director of Endourology
Vice Chair of Quality and Safety
Department of Urology
Sidney Kimmel Medical College at
Thomas Jefferson University Hospital
Philadelphia, PA, USA

**Amanda P. Hughes, BSN, RN, CNOR**
Clinical Coordinator for Urology
Inpatient Surgical Services
Wake Forest University Baptist Medical Center
Winston-Salem, NC, USA

**Fatima Z. Husain, MD**
USC Institute of Urology
Keck School of Medicine
University of Southern California
Los Angeles, CA, USA

**Alabdulaali Ibrahim, MD**
Consultant of Urology
Department of Surgery
Prince Mohammed Bin Abdulaziz Hospital
Riyadh, Saudi Arabia

**Johann P. Ingimarsson, MD**
Clinical Assistant Professor
Maine Medical Center and Tufts School of Medicine
Division of Urology
Portland, ME, USA

**Rita P. Jen, MD, MPH**
Resident Physician
Department of Urology
University of Michigan Health System
Ann Arbor, MI, USA

**Wooju Jeong, MD**
Senior Urologist
Vattikuti Urology Institute
Department of Urology
Henry Ford Health System
Detroit, MI, USA

**Ghalib A. Jibara MD, MPH**
Resident Physician in Urology
Department of Surgery
Division of Urology
Duke University Hospital
Durham, NC, USA

**J. Stephen Jones, MD, MBA**
President Cleveland Clinic Regional Hospitals and Family Health Centers
Professor and Horvitz/Miller Distinguished Chair in Urological Oncology
Department of Urology
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, OH, USA

**Tonye A. Jones, MD**
Urology Resident
UCLA Department of Urology
Los Angeles, CA, USA

**Gerald H. Jordan, MD**
Professor Emeritus
Department of Urology
Eastern Virginia Medical School
Norfolk, VA, USA

***Adrian D. Joyce, MS, FRCS(Urol)***
Honorary Consultant in Urology
Department of Urology
St James' University Hospital
Leeds, UK

***Ilan Z. Kafka, MD***
Endourology/Minimally Invasive
Surgery Fellow
Department of Urology
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

***Kamaljot S. Kaler, MD***
Fellow
Department of Urology
University of California
Irvine, CA, USA

***Panagiotis Kallidonis, MD, PhD, FEBU***
Assistant Professor
Department of Urology
Laparoscopy and Lithiasis Unit
University Hospital of Patras
Rion, Patras, Greece

***Wissam Kamal, MD***
Consultant Urological Surgeon
Department of Urology
Laparoscopy and Lithiasis Unit
University Hospital of Patras
Rion, Patras, Greece

***Jihad H. Kaouk***
Cleveland Clinic
Glickman Urological and Kidney Institute
Cleveland, OH, USA

***Adam G. Kaplan, MD***
Fellow in Endourology, Laparoscopy and
Robotic Surgery
Division of Urologic Surgery
Duke University Medical Center
Durham, NC, USA

***Ahmet Karakeci, MD***
Assistant Professor (International Observer)
Department of Urology
Wake Forest University Baptist Medical Center
Winston-Salem, NC, USA

***Dimitrios Karnabatidis, MD, PhD***
Professor
Department of Radiology
University Hospital of Patras
Rion, Patras, Greece

***Parviz K. Kavoussi, MD, FACS***
Reproductive Urologist
Department of Reproductive Urology
Austin Fertility & Reproductive
Medicine/Westlake IVF;
Adjunct Assistant Professor
Department of Urology
University of Texas Health Sciences
Center at San Antonio
Austin, TX, USA

***Yoshihide Kawasaki, MD***
Assistant Professor
Department of Urology
Tohuku University Graduate School of Medicine
Sendai, Miyagi, Japan

***Francis X. Keeley, Jr., MD, FRCS(Urol)***
Consultant Urologist
Bristol Urological Institute
Bristol, UK

***Michael J. Kennelly, MD, FPMRS, FACS***
Professor
Department of Urology and Gynecology
Women's Center for Pelvic Health
Atrium Health
Charlotte, NC, USA

***Eric H. Kim, MD***
Division of Urologic Surgery
Washington University School of Medicine
St. Louis, MO, USA

***Fernando J. Kim, MD, MBA, FACS***
Professor of Surgery
Division of Urology
Urology-Denver;
Chief of Urology
Denver Health Medical Center
Denver, CO, USA

***Hidefumi Kinoshita, MD, PhD***
Professor
Department of Urology and Andrology
Kansai Medical University Hospital
Hirakata, Osaka, Japan

***John J. Knoedler, MD***
Assistant Professor of Surgery
Division of Urology
Penn State Milton S. Hershey
Medical Center
Hershey, PA, USA

**Bodo E. Knudsen, MD, FRCSC**
Associate Professor
Department of Urology
The Ohio State University Wexner Medical Center
Columbus, OH, USA

**Dimitrios Kotsiris, MD**
Urology Specialist
Department of Urology
Laparoscopy and Lithiasis Unit
University Hospital of Patras
Rion, Patras, Greece

**R. Caleb Kovell, MD**
Assistant Professor of Clinical Urology in Surgery
Department of Urology
University of Pennsylvania
Philadelphia, PA, USA

**Amy E. Krambeck, MD**
Michael O. Koch Professor of Urology
Department of Urology
Indiana University
Indianapolis, IN, USA

**Jessica E. Kreshover, MD, MS**
Assistant Professor of Urology
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

**M. Pilar Laguna, MD, PhD**
Professor of Uro-oncology
Department of Urology
AMC University of Amsterdam
Amsterdam, The Netherlands

**Weil R. Lai, MD**
Clinical Instructor
Fellow
Department of Urology
Tulane University School of Medicine
New Orleans, LA, USA

**Win Shun Lai, MD**
Resident
Department of Urology
University of Alabama at Birmingham
Birmingham, AL, USA

**Michael Lam, MD**
Resident in Urology
Department of Urology
Oregon Health and Science University
Portland, OR, USA

**Daniel J. Lama, MD**
Resident
Division of Urology
University of Cincinnati School of Medicine
Cincinnati, OH, USA

**Jaime Landman, MD**
Professor
Chair
Department of Urology
University of California
Irvine, CA, USA

**Dirk Lange, PhD**
Associate Professor
Department of Urologic Sciences
University of British Columbia
Vancouver, BC, Canada

**David A. Leavitt, MD**
Associate Director of Endourology
Director of Laser Surgery
Vattikuti Urology Institute
Henry Ford Health System
Detroit, MI, USA

**Amir H. Lebastchi, MD**
Chief Resident
Department of Urology
University of Michigan Health System
Ann Arbor, MI, USA

**Benjamin R. Lee, MD, FACS**
Professor
Chief
Division of Urology
University of Arizona College of Medicine
Tucson, AZ, USA

**Lucille Lee, MD**
Assistant Professor of Radiation Medicine
Zucker School of Medicine at Hofstra/Northwell
Department of Radiation Medicine
Northwell Health
New Hyde Park, NY, USA

**Evangelos Liatsikos, MD, PhD**
Professor
Department of Urology
Laparoscopy and Lithiasis Unit
University Hospital of Patras
Rion, Patras, Greece

**Estevao Lima, MD, FEBU, PhD**
Director of CUF Urology Department
Portugal and Department of Urology of Braga Hospital;
Professor of Physiology and Urology
Life and Health Sciences Research Institute
Braga;
ICVS/3B's – Associate Lab. Guimarães
Braga;
School of Medicine
University of Minho
Braga, Portugal

**James E. Lingeman, MD, FACS**
Professor of Urology
Department of Urology
Indiana University School of Medicine
Indianapolis, IN, USA

**Richard E. Link, MD, PhD**
Carlton-Smith Endowed Chair in Urologic Education
Associate Professor of Urology
Director
Division of Endourology and Minimally Invasive Surgery
Scott Department of Urology
Baylor College of Medicine Medical Center
Houston, TX, USA

**Michael E. Lipkin, MD**
Associate Professor in Urology
Department of Surgery
Division of Urology
Duke University Medical Center
Durham, NC, USA

**Igor Lobko, MD**
Chief
Division of Vascular and Interventional Radiology
Director
Vascular and Interventional Radiology Fellowship
Department of Radiology
Long Island Jewish Medical Center
New Hyde Park, NY, USA

**Susan MacDonald, MD**
Assistant Professor of Surgery
Division of Urology
Penn State Milton S. Hershey Medical Center
Hershey, PA, USA

**Catriona I. MacRae, MBBS, BSc**
Registrar
Department of Urology
Tauranga Hospital
Tauranga, New Zealand

**Marc D. Manganiello, MD**
Assistant Professor of Urology
Tufts School of Medicine
Lahey Hospital and Medical Center
Boston, MA, USA

**Robert Marcovich, MD**
Associate Professor and Director of Endourology
Department of Urology
University of Miami Miller School of Medicine
Miami, FL, USA

**Leonard S. Marks, MD**
Professor of Urology
UCLA Department of Urology
Los Angeles, CA, USA

**Eugenio Martorana, MD**
Urology Resident
Department of Urology
University of Modena and Reggio Emilia
Modena, Italy

**Alexey G. Martov, MD, PhD, Honored Doctor of Russia**
Professor
Chairman
Department of Urology
Federal Medico-biology Agency;
Professor of Urology
Russian Medical Academy of Postgraduate
Education;
Head of Urology Department
Moscow City Hospital No. 57
Moscow, Russia

**Mahir Maruf, MD**
Research Volunteer
Urologic Oncology Branch
National Cancer Institute
National Institutes of Health
Bethesda, MD, USA

**Thomas Masterson, MD**
Resident
Department of Urology
University of Miami Miller School of
Medicine/Jackson Memorial Hospital
Miami, FL, USA

**Brian R. Matlaga, MD, MPH**
The Stephens Professor
James Buchanan Brady Urological Institute
Johns Hopkins University School of Medicine
Baltimore, MD, USA

**Tadashi Matsuda, MD, PhD**
Professor
Chairman
Department of Urology and Andrology
Kansai Medical University
Hirakata, Osaka, Japan

**Matthew J. Maurice, MD**
Clinical Fellow
Cleveland Clinic
Glickman Urological and Kidney Institute
Cleveland, OH, USA

**Kurt A. McCammon, MD**
Professor
Chairman
Department of Urology
Eastern Virginia Medical School
Norfolk, VA, USA

**Mani Menon, MD**
Chairman
Vattikuti Urological Institute
Detroit, MI, USA

**Salvatore Micali, MD**
Associate Professor of Urology
Department of Urology
University of Modena and Reggio Emilia
Modena, Italy

**Maurice-Stephan Michel, MD**
Full Professor of Urology
Head of Department of Urology
University Medical Centre Mannheim
Heidelberg University
Heidelberg, Germany

**Arkadiusz Miernik MD, PhD, FEBU**
Associate Professor of Urology
Head of Division of Urotechnology
University of Freiburg – Medical Centre
Department of Urology
Freiburg, Germany

**Brian J. Miles, MD**
Professor of Urology
Weill Cornell Medical College
Medical Director of Robotic Surgery
Houston Methodist Hospital
Houston, TX, USA

**Nicole L. Miller, MD**
Associate Professor
Department of Urology
Vanderbilt University Medical Center
Nashville, TN, USA

**Massimo Mischi, PhD, MSc**
Professor of Biomedical Signal Analysis
Director of Biomedical Diagnostics Labs
Department of Electrical Engineering
Eindhoven University of Technology
Eindhoven
Noord-Brabant
The Netherlands

**Dilip K. Mishra, MBBS, MS, MRCS, MCh**
Consultant Urologist
Department of Urology & Center for Minimally Invasive Endourology
Global Rainbow Healthcare
Agra, India

**Shashikant Mishra, MS, DNB(Urol)**
Consultant Urologist
Department of Urology
Muljibhai Patel Urological Hospital
Nadiad, Gujarat, India

**Akira Miyajima, MD**
Professor and Chairman
Department of Urology
Tokai University School of Medicine
Isehara, Kanagawa, Japan

**Anthony D. Mohabir, MD**
Consultant Urology
Division of Vascular and Interventional Radiology
Department of Radiology
Long Island Jewish Medical Center
New Hyde Park, NY, USA

**Robert Moldwin, MD**
Director of Pelvic Pain Treatment Center
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
New Hyde Park, NY, USA

**Manoj Monga, MD**
Professor of Surgery/Urology
Director of the Stevan Streem Center of Endourology & Stone Disease
Center of Endourology and Stone Disease
The Cleveland Clinic
Cleveland, OH, USA

**Bradley A. Morganstern, MD**
Assistant Professor of Pediatric Urology
Chief, Pediatric Urology at Children's Hospital
of Georgia
Medical College of Georgia
Augusta University
Augusta, GA, USA

**Piruz Motamedinia, MD**
Assistant Professor
Department of Urology
Yale University
New Haven, CT, USA

**Ravi Munver, MD, FACS**
Professor
Vice Chairman
Department of Urology
Hackensack University Medical Center
Hackensack, NJ, USA

**Stephen Y. Nakada, MD, FACS**
Professor
Chairman
The David T. Uehling Chair of Urology
Departments of Urology, Radiology and Medicine
University of Wisconsin School of Medicine
and Public Health;
Chief of Service
Department of Urology
UW Health
Madison, WI, USA

**Shyam Natarajan, PhD**
Adjunct Assistant Professor
Department of Urology and Bioengineering
University of California
Los Angeles, CA, USA

**Oktay Nazli, MD**
Professor
Department of Urology
School of Medicine
Ege University
İzmir, Turkey

**Andreas Neisius, MD**
Associate Professor of Urology
Department of Urology
Brüderkrankenhaus Trier
Johannes Gutenberg University
Mainz, Germany

**Christopher Netsch, MD, FEBU**
Assistant Professor of Urology
Fellow in Endourology
Consultant
Department of Urology
Asklepios Klinik Barmbek
Hamburg, Germany

**Naren Nimmagadda, MD**
Resident Physician
Department of Urology
Massachusetts General Hospital
Boston, MA, USA

**Victor W. Nitti, MD**
Professor of Urology and Obstetrics
and Gynecology
Vice Chairman
Department of Urology;
Director
Female Pelvic Medicine and
Reconstructive Surgery
Department of Urology
New York University Langone Medical Center
New York, NY, USA

**Charles U. Nottingham, MD**
Resident Physician
Section of Urology
Department of Surgery
University of Chicago Medicine
Chicago, IL, USA

**Yasser A. Noureldin, MD, MSc, PhD**
Lecturer
Department of Urology
Benha Faculty of Medicine
Benha University
Benha, Egypt

**Yaw A. Nyame, MD, MBA**
Resident
Department of Urology
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, OH, USA

**Zeph Okeke, MD**
Associate Professor
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

**Zhamshid Okhunov, MD**
Endourology Fellow
Department of Urology
University of California
Irvine, CA, USA

**Carol Olsen, MSN, RN, CURN**
Director
System, Urology Clinical Services
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

**Michael C. Ost, MD**
Chief
Division of Pediatric Urology
Children's Hospital of Pittsburgh of UPMC;
Associate Professor
University of Pittsburgh School of Medicine;
Vice Chairman
Department of Urology
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

**Kenneth T. Pace, MD, MSc, FRCSC**
Vice Chief of Surgery
Head, Division of Urology
Researcher, Keenan Research Centre
Li Ka Shing Knowledge Institute
St. Michael's Hospital;
Associate Professor
Department of Surgery
University of Toronto
Toronto, ON, Canada

**Greg Palleschi, MD**
Assistant Professor
Department of Anesthesiology
Zucker School of Medicine at Hofstra/Northwell
New York, NY, USA

**Lane S. Palmer, MD**
Professor of Urology and Pediatrics
Chief, Division of Pediatric Urology
Cohen Children's Medical Center of New York
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

**Ricardo Palmerola, MD**
Fellow, Female Pelvic Medicine and
Reconstructive Surgery
New York University Langone Medical Center
New York, NY, USA

**Shu Pan, MD**
Resident
Department of Urology
Yale University
New Haven, CT, USA

**Anup Patel, BSc, MBBS, FRCS, MS, FRCS(Urol)**
Consultant Urological Surgeon
London, UK

**Manish N. Patel, MD**
Fellow in Endourology
Wake Forest University School of Medicine
Department of Urology
Winston-Salem, NC, USA

**Roshan Patel, MD**
Endourology Fellow
Department of Urology
University of California
Irvine, CA, USA

**Ryan F. Paterson, MD, FRCSC**
Assistant Professor
Department of Urologic Sciences
University of British Columbia
Vancouver, BC, Canada

**Margaret S. Pearle, MD, PhD**
Professor
Vice-Chair
Department of Urology
University of Texas Southwestern Medical Center
Dallas, TX, USA

**Renato N. Pedro, MD, PhD**
Lithotripsy Center Coordinator – AME/SBO
UNICAMP;
Professor of Urology
Faculdade de Medicina São Leopoldo Mandic
Campinas, Brazil

**Aleš Petřík, MD, PhD**
Assistant Professor
Department of Urology
Hospital Ceske Budejovice
Ceske Budejovice;
Charles University,
1st Faculty of Medicine
Prague, Czech Republic

**John Phillips, MD, FACS**
Residency Program Director
New York Medical College

Department of Urology
Valhalla, NY, USA

**Giovannalberto Pini, MD**
Urologist
Laparoscopy & Robotic Section
Department of Urology
San Raffaele Turro Hospital
Milan, Italy

**Peter A. Pinto, MD**
Urologic Oncology Branch
National Cancer Institute
National Institute of Health
Bethesda, MD, USA

**Giacomo Maria Pirola, MD**
Urology Resident
Department of Urology
University of Modena and Reggio Emilia
Modena, Italy

**Thomas J. Polascik, MD, FACS**
Professor of Surgery
Director, Urologic Oncology Fellowship
Director, GU program on Focal Therapy
Duke Comprehensive Cancer Center
Duke Cancer Institute
Duke University
Durham, NC, USA

**James R. Porter, MD**
Director, Robotic Surgery
Providence Health and Services
Swedish Urology Group
Seattle, WA, USA

**Louis Potters, MD, FACR, FASTRO**
Professor
Chairperson
Department of Radiation Medicine
Northwell Health
New Hyde Park, NY, USA

**Glenn M. Preminger, MD**
James F. Glenn Professor of Urology and Chief
Division of Urology
Department of Surgery
Duke University Medical Center
Durham, NC, USA

**Ali Abdel Raheem, MD, PhD**
Consultant of Uro-oncology
Minimally Invasive Urological Surgery Unit
Tanta University Hospital
Tanta, Arab Republic of Egypt

**Arun Rai, MD**
Resident
Scott Department of Urology
Baylor College of Medicine
Houston, TX, USA

**Soroush Rais-Bahrami, MD**
Assistant Professor of Urology and Radiology
Director, UAB Program for Personalized
Prostate Cancer Care
Departments of Urology and Radiology
University of Alabama at Birmingham
Birmingham, AL, USA

**Rajan Ramanathan, MD**
Professor of Surgery
Department of Urology
Glickman Urological and Kidney Institute
Cleveland Clinic
Cleveland, OH, USA

**Daniel Ramirez, MD**
Urology Associates of Nashville
Nashville, TN, USA

**Dima Raskolnikov, MD**
Resident
Department of Urology
University of Washington
Seattle, WA, USA

**Jens Rassweiler, MD, FRCS(Glasg)**
Professor of Urology
Head of Department of Urology
SLK Kliniken Heilbronn
University of Heidelberg
Heidelberg, Germany

**Marie-Claire Rassweiler-Seyfried, MD, FEBU**
Consultant of Urology
Department of Urology
University Medical Centre Mannheim
Mannheim, Germany

**Ardeshir R. Rastinehad, DO, FACOS**
Associate Professor of Urology
and Radiology
Director of Focal Therapy and Interventional
Urologic Oncology
Department of Radiology and Urology

Icahn School of Medicine at Mount Sinai
New York, NY, USA

***A. Andrew Ray, MD, MSc, FRCSC***
Adjunct Lecturer
University of Toronto
Royal Victoria Regional Hospital
Barrie, ON, Canada

***Hassan Razvi, MD, FRCSC***
Professor
Chair
Division of Urology
Schulich School of Medicine and Dentistry
Western University
London, ON, Canada

***Christopher R. Reynolds***
Fellow
Robotics and Minimally Invasive Surgery
Wake Forest Baptist Medical Center and Wake Forest School of Medicine
Winston-Salem, NC, USA

***Koon Ho Rha, MD, FACS, PhD***
Professor of Urology
Department of Urology
Severance Hospital
Yonsei University College of Medicine
Seoul, South Korea

***Kyle A. Richards, MD, FACS***
Assistant Professor
Department of Urology
University of Wisconsin-Madison
Madison, WI, USA

***Lee Richstone, MD***
Chief of Urology
The Arthur Smith Institute for Urology
Zucker School of Medicine at Hofstra/Northwell
Lake Success, NY, USA

***Manuel Ritter, MD***
Associate Professor
Department of Urology
University Medical Centre Mannheim
Heidelberg University
Heidelberg, Germany

***Pedro L. Rodrigues***
Life and Health Sciences Research Institute
ICVS/3B's - Associate Lab. Guimarães
Braga;
2Ai – Polytechnic Institute of Cávado and Ave
Barcelos, Portugal

***Dayron Rodríguez, MD, MPH***
Resident in Urology
Harvard Massachusetts General Hospital
Program in Urology
Boston, MA, USA

***Craig G. Rogers, MD***
Director of Renal Surgery
Vattikuti Urology Institute
Henry Ford Hospital
Detroit, MI, USA

***Daniel Rosen, MD***
Resident
Department of Urology
Icahn School of Medicine at Mount Sinai
New York, NY, USA

***Ornob Roy, MD***
Assistant Professor of Urology
Carolinas Medical Center
Charlotte, NC, USA

***Daniel B. Rukstalis, MD***
Professor
Department of Urology
Wake Forest University School of Medicine
Winston-Salem, NC, USA

***Matthew P. Rutman, MD***
Associate Professor of Urology at CUMC
Director of Voiding Dysfunction and Female Urology
Columbia University
New York, NY, USA

***Ravindra B. Sabnis, MS, MCH***
Chairman
Department of Urology
Muljibhai Patel Urological Hospital
Nadiad, Gujarat, India

***Simpa S. Salami, MD, MPH***
Assistant Professor
Department of Urology
University of Michigan
Ann Arbor, MI, USA

***Francisco J.B. Sampaio, MD, PhD***
Full Professor and Chairman
Urogenital Research Unit

State University of Rio de Janeiro;
National Council for Scientific and Technological Development – CNPq
Rio de Janeiro, Brazil

**Jaspreet S. Sandhu, MD**
Associate Attending Urologist
Department of Surgery
Urology Service
Memorial Sloan Kettering Cancer Center
New York, NY, USA

**Jeffrey S. Schachar, MD**
Fellow
Female Pelvic Medicine and Reconstructive Surgery
Cleveland Clinic Florida
Weston, FL, USA

**Douglas S. Scherr, MD**
Ronald Stanton Clinical Scholar in Urology
Professor of Urology
Clinical Director, Urologic Oncology
Weill Cornell Medicine
New York Presbyterian Hospital
New York, NY, USA

**John R. Schwabe, MD**
Resident Physician
Wayne State University Department of Urology
Detroit, MI, USA

**Zeyad Schwen, MD**
Resident
James Buchanan Brady Urological Institute
Johns Hopkins School of Medicine
Baltimore, MD, USA

**Cesare M. Scoffone, MD**
Head of the Department of Urology
Cottolengo Hospital
Torino, Italy

**Michelle Jo Semins, MD**
Assistant Professor
Department of Urology
University of Pittsburgh School of Medicine
Pittsburgh, PA, USA

**Ojas Shah, MD**
George F. Cahill Professor of Urology
Director
Division of Endourology and Stone Disease
Department of Urology
Columbia University Irving Medical Center
Columbia University College of Physicians and Surgeons
New York, NY, USA

**Paras H. Shah, MD**
Urologist
Department of Urology
Mayo Clinic
Rochester, MN, USA

**John M. Shields, MD**
Adjunct Clinical Post Doctorate
Minimally Invasive Surgery and Endourology Fellow
Department of Urology
University of Florida
Gainesville, FL, USA

**Pratik A. Shukla, MD**
Radiology Resident
Division of Vascular and Interventional Radiology
Department of Radiology
Mount Sinai Beth Israel
New York, NY, USA

**David N. Siegel, MD, FSIR**
Interventional Radiologist
Vice Chairman, Clinical Affairs-LIJMC
Department of Radiology- Northwell Health
Associate Professor of Radiology
Zucker School of Medicine at Hofstra/Northwell
New Hyde Park, NY, USA

**Mark V. Silva, MD**
Resident
Department of Urology
Columbia University Irving Medical Center/
NewYork-Presbyterian Hospital
Columbia University College of Physicians and Surgeons
New York, NY, USA

**Maximiliano Lopez Silva, MD**
Staff, Urology
Clínica San Camilo;

# Foreword

"Endourology" was the 1978 branding brainchild of Elwin Fraley, Arthur Smith, and Paul Lange.[1] Most felt that the Minnesota cold had finally gone beyond their woolen headgear to create a "brain freeze" of monumental proportions. Fast forward nearly 40 years and, today, endourology has become urology. Diagnostically, from the urethral meatus to the uppermost renal calyx, the entire urogenital tract can be revealed in great detail using both endoscopic and sophisticated imaging technologies. Therapeutically, urologists of talent, innovation, and persistence have supplanted standard incisional access with an endoscopic, image-guided, or combined approach.

If you are reading this Foreword then you are reading a book that contains every aspect of urology and how it is benefited by a minimally invasive (i.e. percutaneous, ureteroscopic, laparoscopic, robotic) or noninvasive image-guided (i.e. shock-wave lithotripsy, focal therapy) approach. The authors are an international *Who's Who* of experts in endourology. The content ranges from basic to futuristic endourology. In 166 chapters, the latest advances in antegrade and retrograde endoscopic nephrostomy, laparoendoscopic single-site surgery, and robotic procedures as well the newest image-guided therapies are clearly detailed and illustrated both in photographs and often by instructional video demonstrations.

A wise mentor[2] once advised me: "You are only as good as tomorrow." That single sentence should haunt each of us as we arise every morning to provide relief to those who suffer. To that end, we must seek methods to relieve suffering rather than cause it, to heal without harming, to cure without substituting one malady for another. Endourology empowers each of us to provide all individuals seeking our care with a kinder, gentler solution to their urological problems. In the first part of the twentieth century, Sir William Osler opined: "Diseases that harm require treatments that harm less."[3] A century later, his dictum has been largely realized in the practice of endourology.

My heartfelt congratulations go out to Drs Smith, Badlani, Kavoussi, Preminger, and Rastinehad, who have provided a comprehensive guide of immense value to me, to you, and to all of our patients. Read *Smith's Textbook of Endourology* well, apply its principles earnestly, and, if opportunity presents, seek to further innovate and build on its contents. The text is not an end in and of itself; rather, it is another paver in the surgical journey in which each of us plays a role — using techniques borne of today's technology to proceed to further reduce the burden of the "surgical" cure we are obligated to apply.

Ralph V. Clayman

# Preface

The cover of this textbook synthesizes the concepts of endourology. In order to perform endoscopic surgery one needs access to the organ and various forms of energy to facilitate access, control bleeding, and obliterate tissues. These goals can only be accomplished with appropriate devices. Fortunately, evolving technology allows the manufacture of improved devices. It is essential for endourologists to keep abreast of these advances. The fourth edition of this book accomplishes this with an update of the existing chapters by the original authors or complete revision by new authors.

In 1978 the concept of endourology was launched. It was defined as closed, controlled manipulation within the urinary tract. The word "closed" was used to indicate either a minimal incision or no incision at all and the control was achieved either endoscopically or by noninvasive imaging. Until then, residents had been taught that the only way to have good exposure was through a large incision. Now the ultimate goal is good exposure with no incision at all. This is achieved by utilizing a combination of endoscopy and the new modalities of imaging. There are now relatively few accepted open urological procedures and this has had the gratifying result of a dramatic decrease in the morbidity of our patients undergoing treatment.

In this era of fewer working hours for residents, the amount of time that the residents spend in the operating room has decreased dramatically and the necessary skills have to be taught using a combination of additional educational modalities. In addition to books and journals, there are an abundance of videos on surgical techniques, animal laboratories, teaching models, and virtual reality simulators. Fortunately, endourologic techniques are uniquely suited to these modalities and the student can become quite adept by using them before being instructed in the operating room.

As the technology has evolved, courses have been organized by the Endourology Society to train not only the residents and fellows, but also the practicing urologist so that their "learning curve" can be accelerated, and they can then use these techniques with the required expertise. In addition, the Endourology Society has developed the *Journal of Endourology* and the *Journal of Endourology Case Reports* to update urologists on the latest technology. The *Journal of Endourology* allows the members access the *Journal of Videourology* which features videos of new and established techniques on the computer or tablet.

This textbook consists of two volumes. Volume 1 is on stones of the upper tract. Volume 2 is on robotic and laparoscopic surgery and image-guided diagnostic and therapeutic techniques together with minimally invasive therapy of the lower urinary tract. Volume 1 consists of five sections. Section 1 discusses the basic principles. Section 2 is devoted to percutaneous renal surgery. Section 3 discusses the intricacies of ureteroscopy. Section 4 is on shock-wave lithotripsy. We are cognizant of the fact that there is no single modality for the treatment of stones and hence Section 5 describes the management of the patient with various stone-related problems in a composite format.

Volume 2 covers robotic and laparoscopic surgery. At present, there is very little difference between the techniques and that which there is is primarily related to technical experience, availability of the robot, and financial considerations. Sections 6 and 7 discuss image-guided diagnostics and therapeutics. This is an important addition to our *Textbook of Endourology*, as it is an essential component of the armamentarium of the practicing urologist, particularly as we move into the era of "no incision." If the procedures described in this section are not performed by urologists, then they will be taken over by radiologists. This in turn will result in the loss of continuity of care of our patients.

I would like to thank each of the contributors for the many hours they have devoted to writing, illustrating, and creating videos for their chapters. Hopefully, they will be as delighted with the results as the editors and publishers of this textbook. I am also deeply indebted to my co-editors, who have reviewed, edited, and re-reviewed chapters countless times. Thanks to their families as well, as the time spent on the book could have been devoted to them. The staff at Wiley Blackwell and the project manager Mirjana Misina have been highly professional and encouraging. When one deals with a large organization, it is reassuring to know that as a book bounces from one stage to the next there has been a "continuity of care throughout the operation." They are a great team and we appreciate all the help we received from them.

Finally, I would like to thank my wife, Kay, who inspired me to edit this fourth edition and has repeatedly helped me with this and countless other projects throughout my academic career. If I am regarded as the "father" of endourology, she is unquestionably the "mother" who has helped to nurture this field of urology.

June 2018 *Arthur D. Smith*

# About the Companion Website

This book is accompanied by a companion website:

**www.wiley.com/go/smith/textbookofendourology**

The website includes:

- Over 100 videos showing procedures as described in the book
- PowerPoints of all figures from the book for downloading

### Single-site robots

Robotic technology was first reported to have been incorporated with single-site surgery in 2011 using the da Vinci Single-Site© surgical platform (Intuitive Surgical, Sunnyvale, CA, USA), which aimed to improve the technical limitations of laparoscopic single-site surgery including external clashes, poor visualization of critical structures, and surgeon fatigue [1]. In 2015 a systematic review showed that the da Vinci surgical platform had proven to be a valuable asset in single-site surgery, owing to the combination of robot use and dedicated single incision; the main reported limitation was the lack of an EndoWrist [2].

The da Vinci single port (SP) is Intuitive Surgical's new surgical platform for single-incision surgery, and gained US Food and Drug Administration approval in early 2014. It is composed of a three-dimensional (3D) high-definition (HD) camera and three fully articulated instruments, all in a 25 mm port. The fully wristed EndoWrist SP instruments have two more degrees of freedom than the da Vinci Single-Site instruments. The surgeon controls the instruments and the endoscope while seated at the da Vinci Surgical System console. Intuitive Surgical plans not to release it onto the market until it has been made fully compatible with the latest da Vinci Xi robot. This will require product refinements, supply chain optimization, and additional regulatory clearances [3]. The system is designed for urologic minimally invasive procedures that are already performed via a single incision. Major urologic procedures have been successfully completed using the da Vinci SP without conversions [4].

A second single-port system is called Single Port Orifice Robotic Technology (SPORT™; Titan Medical, Toronto, ON, Canada; see Figures 74.1 and 74.2). The system utilizes a 25 mm single-access port which contains a 3D HD vision system and interactive multi-articulating instruments, and a highly ergonomic surgeon workstation that provides the surgeon with an interface to the robotic platform, as well as a 3D endoscopic view inside the patient's body cavity during minimal invasive surgical procedures. It is expected to be commercially available in late 2019. The first targets of the SPORT system are gynecologic, gastrointestinal, and urologic procedures [5].

In December 2015 the building of the first SPORT Surgical Systems to include both the work station and the patient cart was announced. These will undergo extensive testing as a part of engineering verification (EV). These two EV systems will be tested to measure performance in relation to design specifications and to measure compliance with regulatory guidelines. These EV systems were precursors of the systems that were made ready in early 2016 for the first in-human trials. The multi-articulating, interactive, snake-like instruments are designed to couple with removable and sterile single-patient-use robotic tools that provide first-use quality in every case and eliminate the need for instrument reprocessing. The use of reposable (re-usable for a specific number of uses) robotic instruments and single-patient-use tools allows more use cases for each robotic instrument, thus reducing the per-case cost. The robotic platform is also designed to include a mast, a boom, and wheels for optimal configurability for a variety of surgical indications and the ability to be maneuvered around the operating room and surgical centers where applicable [5].

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.

Companion website: www.wiley.com/go/smith/textbookofendourology

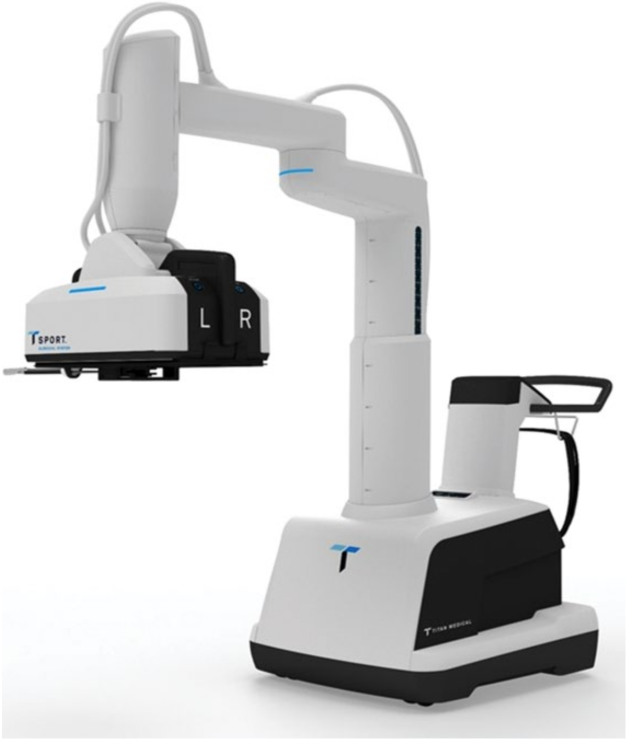

**Figure 74.1** The patient cart of the SPORT system. *Source:* Titan Medical, Inc., Canada. Reproduced with permission of Titan Medical, Inc.

Another single-port robot is the SurgiBot (TransEnterix, Morrisville, NC, USA; Figures 74.3 and 74.4). It enhances laparoscopic surgery through robotic assistance, while allowing the surgeon to remain in the sterile field, at the patient's side. It is composed of an integrated 3D HD camera for HD images with depth perception and delivers up to three articulating instruments through a single incision. One of its main advantages is that it has minimal reliance on surgical assistants and staff [6].

The Avicenna roboflex flexible uretroscopy robot (Elmed, Turkey) consists of a console and a manipulator. The hand piece of the scope is locked to the robotic arm. The surgeon at the console can control two joysticks to manipulate the rotation, deflection, and in-and-out movements of the endoscope. A central wheel enables fine tuning of deflection inside the collection system. The surgeon can rotate robotically 440°. This minimizes the torsion risk of the endoscope. Laser fiber can be remotely moved in and out which is very helpful for providing a suitable distance between the stone and the tip of the laser fiber. Software prevents firing of the laser shot when the laser tip is very close to the endoscope to prevent damage. The integrated water pump can also be adjusted remotely. In this way it is possible to treat a stone with a minimal flow rate and to provide low-pressure lithotripsy [7]. A human trail on 81 patients showed efficacy, safety, and a significant improvement in ergonomics [8].

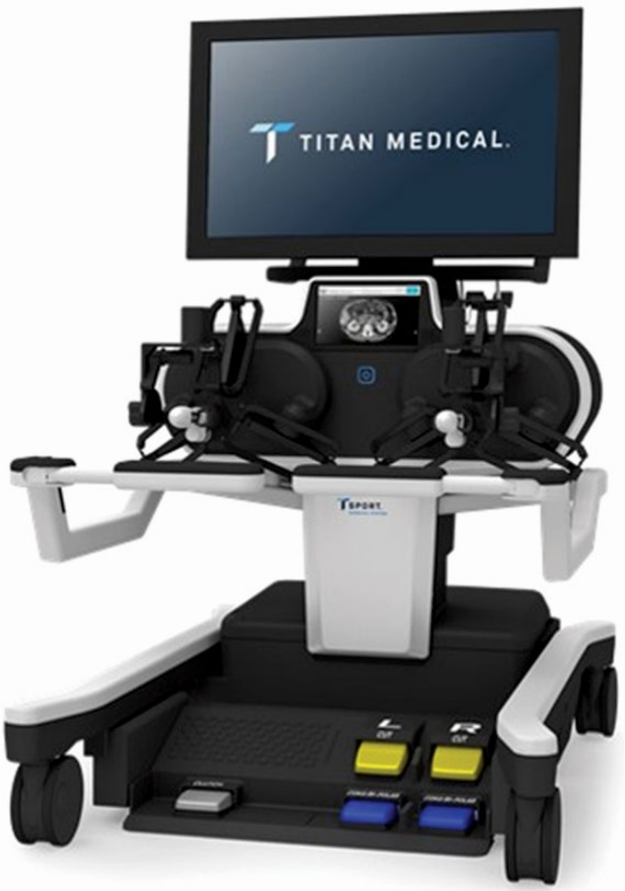

**Figure 74.2** The surgeon console of the SPORT system. *Source:* Titan Medical, Inc., Canada. Reproduced with permission of Titan Medical, Inc.

The last robot reaching the market soon and utilizing a single port (natural orifice transluminal endoscopic surgery, or NOTES) is the Flex (Medrobotics Corp., Raynham, MA, USA). It utilizes a highly articulated multilinked scope that can be steered along nonlinear, circuitous paths in a way that is not possible with traditional, straight scopes. The maneuverability of the scope is derived from its numerous mechanical linkages with concentric mechanisms. This enables surgeons to perform minimally invasive procedures in places that were previously difficult or impossible to reach [9]. Surgeons can operate through a single access site and direct the scope to the surgical target. Once positioned, the scope can become rigid, forming a stable surgical platform from which the surgeon can pass two flexible surgical instruments. The system includes on-board HD visualization to give surgeons a clear view of the navigation path and surgical site [9].

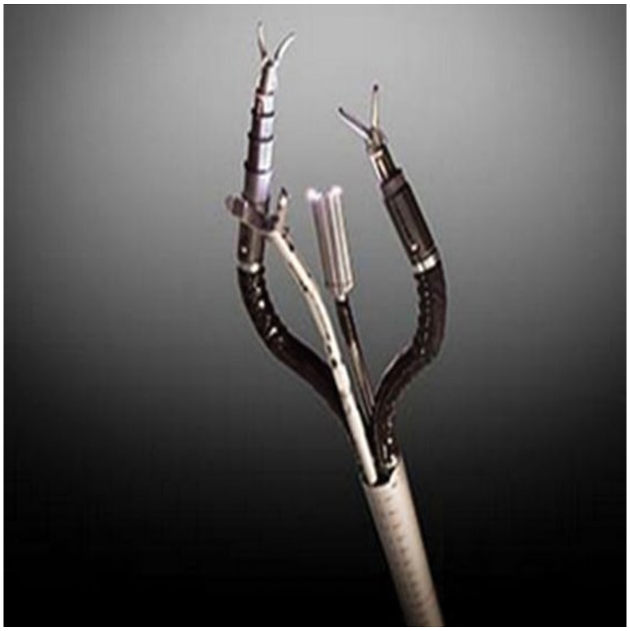

**Figure 74.4** The SurgiBot patient-side single port. *Source:* TransEnterix, USA. Reproduced with permission of TransEnterix, USA.

Approval was achieved in Europe in 2014, and aim for a first limited commercial launch on selected European markets [10].

## Multiple-site robots

Figure 74.5 shows the ALF-X system, developed by Sofar S.p.A. (Trezzano Rosa, Milan, Italy) and currently owned by TransEnterix. It is a multiport remotely operated robotic system that utilizes a remote control station and robotic arms. Three system features include haptic feedback, an eye-tracking system, and reusable endoscopic instruments. Haptic feedback allows the surgeon to "feel" the force employed through the instruments and the natural resistance of the tissues. The eye-tracking system allows accurate movement of the 3D endoscope. The first targets of the system were gynecology, urology, and thoracic surgery procedures. The ALF-X gained CE market approval in 2011 [11].

ALF-X has a comprehensive set of multipurpose tools that can be sterilized, which allows a significant cost reduction in the field of robotic surgery and makes it more accessible. Another feature is that there is no need to dock the robotic arm to a trocar, which decreases the operative time and facilitates easy patient repositioning intraoperatively. The console handpiece is similar to that for laparoscopic instruments which facilitates easy familiarization and a shorter learning curve.

The system can handle up to four arms and each manipulating arm is carried by its own patient side cart. The tools are introduced through standard 5 mm laparoscopy ports, making it possible to maneuver both laparoscopic and robotic instruments simultaneously. Since the beginning of clinical trials in 2013, a few studies have shown safety and feasibility in the treatment of various gynecological conditions [12–14].

The second multiport system is Surgenius (Surgica Robotica S.p.A., Trieste, Italy). The system consists of six degrees of freedom (DOF) arms, equipped with six DOF tip-force sensors, providing haptic feedback to the operator. The robotic arms can be positioned freely around the surgical bed, as they are independent of each other. They can be equipped with Surgica Robotica's high-dexterity instruments, which allow great precision and wide maneuverability. The surgical system can be configured with the number of robotic arms that is necessary for the intervention, from one single arm to as many arms as can fit around the surgical bed. Surgenius gained CE market approval in 2012 [15].

The Bitrack system by Rob Surgical Systems S.L. (Catalonia, Spain) was designed to cover current limitations in laparoscopic surgery, like for example a system's lack of flexibility and modularity, and the set-up time. The prototype for the robot was finished in early 2015 and moved into the clinical validation phase to gain approval for the European and US markets. Rob Surgical Systems expects to obtain European approval in 2018 [16, 17].

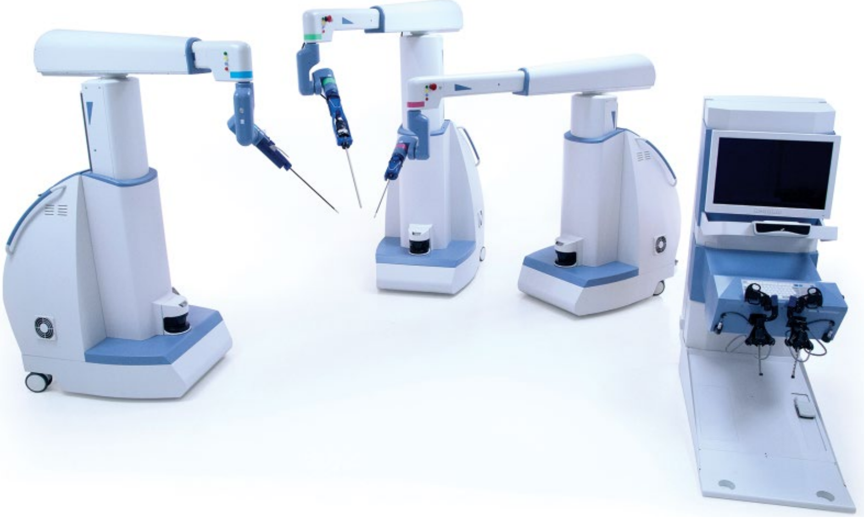

**Figure 74.5** The ALF-X. *Source:* TransEnterix, USA. Reproduced with permission of TransEnterix, USA.

The Chinese surgical robotic system Micro Hand S was invented at Tianjin University. It has three main technical advantages. The first is multi-DOF wire transmission, making instruments for minimally invasive surgery with the benefits of no coupled motion, fixation, skid resistance, and anti-looseness more conducive to maintaining accuracy. Second is a reconfigurable layout and implementation of a "slave hand," making the robot "arms" lighter and more adaptable to the needs of the operation. The third is homogeneous control model building technology for hand–eye–instrument motion consistency in the 3D visual environment. The first clinical trials were done in March 2014 and showed the safety and effectiveness of the Micro Hand S in performing robot-assisted minimally invasive surgery [18].

The NeuroArm is a magnetic resonance imaging (MRI)-compatible image-guided computer-assisted device specifically designed for neurosurgery. In 2008 it made history when the robotic system was used to operate on a human patient at the Faculty of Medicine, University of Calgary, Canada. This landmark operation was the first time a robot was used to perform image-guided neurosurgery [19].

End-effectors are equipped with 3D force sensors, providing a sense of touch. The surgeon, seated at the workstation, controls the robot using force feedback hand controllers. The workstation recreates the sight and sensation of microsurgery by displaying the surgical site and 3D MRI displays, with superimposed tools. NeuroArm enables remote manipulation of surgical tools from a control room adjacent to the surgical suite. It was designed to function within the environment of 1.5 and 3.0 tesla intraoperative MRI systems. As NeuroArm is MR-compatible, and stereotaxy can be performed inside the bore of the magnet with near-real-time image guidance. NeuroArm possesses the dexterity to perform microsurgery outside of the MRI system [19].

The DLR Institute of Robotics and Mechatronics in Germany has developed MIRO, a second generation of robot arms for surgical applications. With a low weight of 10 kg and dimensions similar to those of the human arm, the MIRO robot can assist the surgeon directly at the operating table where space is tight. The scope of applications of this robot arm ranges from guiding a laser unit for the precise separation of bone tissue in orthopedics to setting holes for bone screws, robot-assisted endoscope guidance, and minimally invasive surgery. Arms can be mounted directly to the operating table [20].

The DLR also developed a system called MicroSurge, which includes a master console with a 3D display and two haptic devices as well as a teleoperator consisting of three MIRO robot arms. Usually two MIRO arms carry surgical instruments equipped with miniaturized force/torque sensors to capture reaction forces with manipulated tissue. The third MIRO arm can (automatically) guide a stereo video laparoscope. The stereo video stream as well as the measured forces are displayed to the surgeon at the master console. Therefore the surgeon is not limited to seeing but can also experience force feedback from the input devices [21].

The system is designed to be able to perform complex procedures, e.g. beating-heart operations, where the tools and camera are moved synchronously with the heart, to give the surgeon the impression that the heart stands still. The virtual stopping of the heart and lung reduces the trauma to the patient [10].

AVRA Surgical Robotics is developing a surgical robotic system of modular construction which offers a portable lightweight and maneuverable robotic solution not available in any current available systems. The basic AVRA Surgical Robotics System (ASRS) employs four robotic arms with a weight/payload ratio that is unavailable in the current surgical robotics market [22]. This ratio allows robotic applications for a vast range of minimally invasive operations as well as robotic application for potential use in traditional open surgical procedures. ASRS's intelligence is incorporated within the arms and joints. The system can be configured with four or fewer arms and as such can be used, for example, in a single-arm construct with applications such as in-joint orthopedics.

The ASRS arms can be mounted on a patient-side cart, placed next to the operating table, or directly mounted to the operating table as well as attached to an overhead structure. The ASRS surgeon console merges the high-resolution view of the surgical field, the data, information management, and action of the robotic system with the biomedical and IT environment in the operating theater. This console will provide a newly developed human–machine interface (HMI) for the maneuvering of both instruments and the camera head.

## Conclusion

Robot-assisted surgery is a rapidly growing field, helped by continually evolving technology and its use in a wide variety of surgical settings. The near future is packed with a promising number of surgical robotic systems which can give better outcomes. Product costs are expected to go down as more competitors offering distinct technologies enter the market.

The first challenge for the near future will be to adapt the conventional forms of treatment to integrated, computer-assisted alternatives. This requires new training plans for medical staff, and changes in the layout of hospitals to accommodate the new requirements. Without a team that can exploit these opportunities to the fullest, gains from the use of this technology will remain small.

# Training and Credentialing Laparoscopic and Robotic Surgery

*Domenico Veneziano*[1] *& David M. Hananel*[2]

## Surgical training today: a complex scenario

"See one, do one, teach one" has been the mantra of surgical training for decades. Unfortunately, when we ask *where* are we going to see, do, and teach, the answer is often still "the patient." In its early days, laparoscopy was considered too challenging and surgeons asked "why work through a keyhole when you can just walk through the door?" [1]. Indeed, operating through a keyhole adds even more complexity to surgery: fulcrum effect, decreased haptic feedback, and loss of depth perception, to name a few [2]. Despite these challenges, the early 1990s saw rapid acceptance of laparoscopy driven by patient demands: reading and hearing about faster recovery, less pain, and less scarring. The field was caught by surprise and device companies started to provide training courses led by the early adopters. A weekend course was often considered enough by many surgeons to try this new technology at their home institutions. There was no standardized curriculum established and training was performed mainly on porcine models.

The desire to overcome some of the challenges in laparoscopy and an interest in remote surgery to perform operations in underserved or dangerous venues led to research in robotically assisted surgery. These efforts were funded by Defense Advanced Research Projects Agency (DARPA; Arlington, VA, USA) and the National Aeronautics and Space Administration (NASA; Washington DC, USA) [3–5]. This new technology provided the surgeon with stereoscopic vision to reinstate depth perception, hardware compensation of the fulcrum effect via console design, and tremor control and scaled motion to improve the accuracy of instrument movement well beyond what a normal set of hands was capable of. Yet robot-assisted surgery came with its own learning curve in addition to the basics, such as console management, robotic instrument knowledge, docking of the machine, and emergency undocking in case of life-threatening complications. At the same time, complete knowledge of surgical anatomy, procedural skills, and basic surgical principles still had to be properly mastered before dealing with the new technology. Moreover, modern surgery with its complex scenarios has raised the importance of so-called "nontechnical skills" [6] (situational awareness, communication, teamwork, leadership, stress management) in order to safely perform a surgical procedure, in spite of technological advancements.

Whenever we approach mastering something new, scaffolding [7, 8] facilitates acquisition of the required skills. This principle is equally valid whenever we are learning to ride a bicycle or to perform a new surgical intervention. Despite the famous phrase "to err is human," limiting errors and facilitating the correct technique becomes critical in the surgical field, as patients cannot continue to be the training platform.

Simulation has the goal of approaching the same situation multiple times, in order to understand it, apply different strategies to solve it, assess the pros and cons, select a preferred approach, and improve on it in a safe environment. It is widely used in several nonmedical fields to test new products and procedures, improve performance, predict future outcomes, and certify the acquisition of skills. In surgery, shortened hospital stays, shortened residency hours, and the rate at which new procedures and new technologies are introduced translate into a reduced number of operative cases for learners to participate in for any given procedure [9–11].

*Smith's Textbook of Endourology*, Fourth Edition. Edited by Arthur D. Smith, Glenn M. Preminger, Louis R. Kavoussi, and Gopal H. Badlani.
© 2019 John Wiley & Sons Ltd. Published 2019 by John Wiley & Sons Ltd.
Companion website: www.wiley.com/go/smith/textbookofendourology

Moreover, *in situ* skills assessment is challenging and the results of residency training are barely measured or considered in view of becoming a full surgeon. Although the use of simulation could potentially fill these gaps, its application is not yet as standardized or widespread as one would imagine. Indeed, it is used to varying degrees from country to country and even from institution to institution, leading to significant differences in technical and nontechnical skills between young practitioners in the same field.

The American College of Surgeons' Accredited Educational Institutes (ACS-AEI) program was started in 2005 with the aim of providing guidelines and standards for simulation centers inside and outside the United States. The results turned out to be outstanding, and there are currently 94 accredited centers worldwide [12]. Despite the significant inroads, many sim-centers still prefer not to adopt a standardized training model, continuing to create their own model instead.

In Europe simulation is not typically considered a critical part of the urology residency curriculum. In the last decade some countries have adopted standardized training protocols to provide learners with a unified model to follow, preparing them for medical practice. This happened in the Netherlands with the 40 hours program and in the United Kingdom with the "Guidelines for training" [13] written under the auspices of the British Association of Urological Surgeons (BAUS). In Europe, simulation centers are still not common and few universities offer residents a chance to use pelvic trainers or simulators in general. Recognition of the need for deliberate, repeated simulation training and the lack of proper tools has led hands-on training (HoT) sessions to become more and more popular all over Europe. HoTs provide tutoring on dedicated models during congresses and educational events. These sessions use standardized training kits with predefined exercises and learning objectives. The European Urology Residents Education Program (EUREP) [14], flagship training event of the European Association of Urology (EAU), introduced the HoT format into its schedule in 2006 and today attracts hundreds of final-year residents from all over Europe, exposing learners from many countries to a unified training protocol [15].

The Urological Society of Australia and New Zealand (USANZ) streamlined the training regimen with the nSET Program, which includes training activities through the six residency years up to independent clinical practice, including the achievement of primary operator skills for laparoscopic surgery. Technical skills training is still not common practice in Africa, South America, and Asia, where structured technical skills teaching is limited to few training centers and dedicated courses.

Robotic surgery training is not yet formally considered as a part of urological education worldwide and few residents have a chance to perform robot-assisted surgery as first operators before the end of their learning path.

## History of surgical training: a growing field

Although ancient texts, such as the *Sushruta Samhita* from India, laid down in Sanskrit around 500 CE (original date unknown, but thought to go back to 1000 BCE), mention the use of various models to practice surgical skills for speed and accuracy, we will focus on recent history to follow our current model for medical education. Surgical residency as we know it today in the United States began in the early 1900s at Johns Hopkins University in Baltimore, MD, under the guidance of William Halstead. During those formative years, we have evidence that dog labs were used to teach both procedural as well as team-based skills. We also tend to point at flight simulators to make a case for the use of simulation in medicine. Surprisingly, that path began later, in 1929, with the Link Trainer (Figure 75.1) [16], which was instrumental in training young pilots how to land on aircraft carriers.

These early trainers can be compared to the basic skills trainers we see today, such as FLS, BLUS, and E-BLUS (see below) [17–19]. The growth of the Link Trainer into today's full flight simulators and regimented training programs could not have happened without a significant investment by the US Department of Defense (DoD) to develop the science and technology that underlies them.

We can recognize multiple phases in the progression of simulation in healthcare. The initial driver was the promise of objective assessment. In theory, by using virtual reality (VR) for training and assessment, we could measure everything that was represented in the mathematical models. Thus we could look at variables such as time and distance, but also collisions, penetrations, and path lengths, and even the use of energy, radiation, and blood loss. The believers were so excited about the possibilities that the mantra was "build it and they will come." For the first VR simulators to be developed a number of technologies had to evolve. Many of them were supported by the DoD, such as graphics processors, head mounted displays, and haptic interfaces. As these technologies came into existence, by many accounts Dr Richard Satava, a laparoscopic surgeon who at the time was at DARPA, began funding projects in the late 1990s to see if "flight simulators for surgery" were within reach

**Figure 75.1** The Link Trainer.

[20]. Some of these early efforts resulted in a sinus surgery platform [21, 22] and a vascular anastomosis trainer, among others [23, 24].

The second wave came only a few years after that, with the tagline "validate it and they will come." Early validation studies provided much-needed proof of the scientific and educational merits of surgical simulation. The key study which set the standard that many followed was that by Seymour et al. [25]. By that time a number of companies in the United States and abroad had launched commercial products into the market. That opened up the door for the next phase in development: an integrated curriculum, where simulation was one component of the whole. Validation studies gave the new technology legitimacy, while the integrated curriculum concept paved the way for today's comprehensive view: backwards design, predefined learning objectives, assessment tools, part task trainers, human patient simulators, and full procedural VR simulators.

In the last few years the DoD has refocused on medical simulation with significant investment in infrastructure: funding the development of open-standards-based building blocks to support the big picture and exponentially accelerate development. To formalize even more the birth of this new field of medical education and to push its development and widespread, ACS-AEI accredited in 2014 a research fellowship program in education and simulation technologies, to be delivered by selected centers.

## From FLS to the concept of modular hands-on training

When a new surgical intervention has to be learned, there are many topics that need to be addressed. Given a learner's previous experience, some of those may be skipped, some may just need refreshing, and others may require in-depth study and practice. Figure 75.2 provides a picture of the many elements that go into learning a surgical procedure. The concept is based on two principles: first and foremost a focus on patient management; second, bringing all contributors to safely performing a new procedure under one umbrella. This allows the learners to assess what they already are comfortable with, review where they have gaps, and finally layer in the new and difficult components specific to the procedure. The complexity of the procedural training template in Figure 75.2 demonstrates how difficult it is to move from basic clinical knowledge in medicine combined with basic technical skills to complete procedures and finally take on the responsibility of independent patient management. The true value of having a standardized template is to allow academic surgeons from all over the world to collaborate and contribute to this vast endeavor in developing training materials for all procedures [9, 26, 27].

To acquire the technical skills portion of a new procedure, we can often use some of the existing simulators. One of the first simulators to be validated with sufficient

rigor in order to be used for a high-stakes exam was Fundamentals of Laparoscopic Surgery (FLS). It was first proposed at McGill University by Dr Gerry Fried [17], then developed under the auspices of SAGES, and validated in collaboration with the ACS [28]. FLS tasks were thought to reproduce the basic movements used in laparoscopy and were so well planned to be easily adapted to basic skills teaching in other laparoscopic specialties, such as gynecology and urology. FLS was developed to target basic maneuvers and not full procedures. In the United States FLS has been used as a starting point for the creation of the Basic Laparoscopic Urological Skills (BLUS) curriculum. Despite a study [18] showing validity, the BLUS exam is not mandated and is used only by choice at select residency programs. The EAU started to build upon the FLS experience in 2011, when the European Basic Laparoscopic Urological Skills (E-BLUS) [19] exam was given for the first time. E-BLUS is today the only technical skills certification to be mandated by an international urological society. It is made up of four tasks: peg transfer, circle cut, needle guidance, and intracorporeal knot tying (Figure 75.3). Depending on faculty's preference, basic training protocols often include the use of a camera navigation trainer [29] for a 30° laparoscope, although this exercise is not included in the examination. Initially intended as a stand-alone certification program, E-BLUS is rapidly evolving into the first step of a comprehensive pathway, guiding the novice from basic skills to full procedures and mastery.

Modular hands-on training, as depicted in Figure 75.4, suggests approaching technical skills training in three distinct steps: basic (simple skills), intermediate (complex tasks), and advanced (full procedures) [30, 31]. This general concept, in this case applied to laparoscopy, prescribes a logical progression for novices, a learning path to prepare them for mentored cases with patients.

*Basic skills* target fundamental building blocks: simple maneuvers like camera handling, grasping, traction/countertraction, cutting, and single-knot tying, which form the basis of any surgical technique. These are common to different laparoscopic specialties and that's why FLS, originally designed for general surgeons, was so easily adopted by urologists. Given the proven validity of trainers like FLS and E-BLUS, a novice should never learn basic skills on a patient.

*Intermediate training* is much more specialty-specific and focuses on the "complex tasks:" the most challenging steps of full procedures. Indeed, mastering basic skills, as well as practicing complex tasks on bench models, prepares the trainee to approach full procedural, or *advanced training*. At this stage the trainee has to link all the concepts learned along the way in order to perform the whole procedure (making errors, and learning how to recover) in a safe, simulated environment, before working on a real patient. While progressing from basic skills to full procedures, focus shifts to different aspects of surgical education, from technical skills to decision making and patient management, necessitating very different types of simulators.

While laparoscopic basic skills are already well documented and standardized, complex tasks for intermediate training are not yet fully defined and incorporated into validated curricula. Moreover, these are much more challenging to simulate. A first comprehensive curricular implementation exists as a joint effort between the ACS and the Association of Program Directors in Surgery (APDS) as the ACS/APDS Surgery Resident Skills

Curriculum Phases I, II, and III, going from basic steps and tasks to procedures and team-based training [32–35]. Laparoscopic complex tasks according to the American Urological Association (AUA) and the EAU are summarized in Table 75.1. In either case, both American and European Urological societies agree that mastering complex tasks is critical before continuing on to perform complete procedures.

If laparoscopy made control of the instruments more difficult, putting a surgical robot in between surgeon and the instruments created new challenges, still being studied. Regarding basic skills, robotic consoles are explicitly developed to make instrument control much easier, eliminating fulcrum effect and lack of depth perception. On the other hand, becoming proficient on the console itself requires practice. Just like the cockpit of a car, it has few but important controls that need to be internalized so that the operator can focus on the procedure itself. Moreover, robot-assisted surgery requires continuous collaboration between console operator and bedside assistant, necessitating nontechnical skills training. Following on the footsteps of basic laparoscopy curricula, several training models [36] have been suggested for robotic surgery in urology. The first paper about the fundamentals of robotic surgery (FRS) was dated 2014 [37] and describes the process followed to design a basic training curriculum which could address the needs of multiple specialties and their societies. FRS includes cognitive content with pre-, intra- and postoperative activities, psychomotor skills, and team training exercises. To support the FRS curriculum, a physical training dome has been designed in order to place FLS tasks into a tridimensional environment. To maximize repeatability and standardization, the FRS dome with its predefined tasks was also reproduced on virtual platforms. In 2015, Fundamental Inanimate Robotic Skills Tasks (FIRST), a second training model for basic robotic skills, was validated [38]. The study enrolled 96 participants and scored performance in relation to completion time and errors performed on four FLS-inspired inanimate tasks. The most relevant experience in Europe regarding

robotic training was documented in 2015 [39] under the auspices of European Robotic Urology Section (ERUS). The article describes a fellowship curriculum to be carried out at an ERUS-accredited center, which is able to guide attendants in 6 months from VR training platforms up to the successful completion of a robot-assisted radical prostatectomy.

After the completion of a full training curriculum, mentored procedures on the patient can be supervised in robotic surgery thanks to the use of the dual console, which allows the tutor to eventually step into the procedure and help the operator, if needed.

Both in laparoscopy and in robot-assisted surgery, following a step-by-step path will shorten the learning curve, lead to faster mastery of a new surgical procedure, and increase patient safety.

## The science of curriculum development

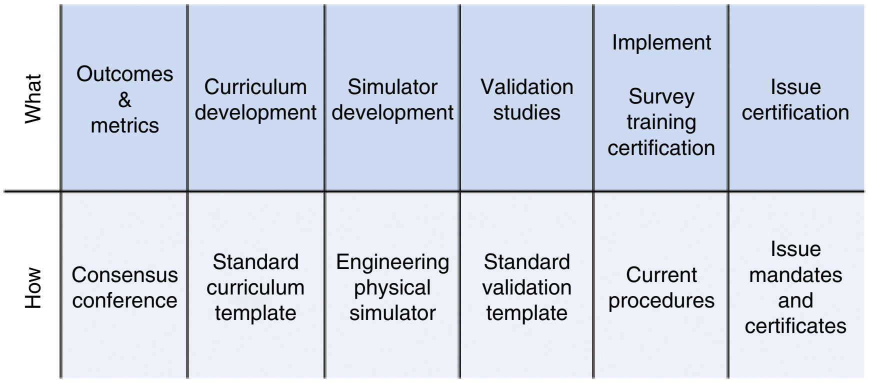
The creation of a comprehensive curriculum requires a rigorous process, beginning with deep insight into the intervention. The process links training outcomes to learning objectives and the validation process to the educational intent [25, 40]. The focus has to be on the curriculum, which in many cases will require a simulator to practice on.

There are three distinct roles in developing curricula: the clinician, the educator, and the developer; it is key that those roles are kept separate. The clinician is the source of all insight into the intervention, the disease, management of the patient, and the underlying basic science. The educator helps with the educational design and creation of valid assessment instruments. Finally the developer addresses content development, which may include simulators. Although the participants may want to play multiple roles in the process, we should resist that and keep these efforts distinct to ensure the best outcome.

One effective template to follow in order to avoid missing any important step is the one described by Richard Satava, named full life-cycle curriculum development [41] (Figure 75.5). The template describes a well-defined process, which begins and ends at the same point (full life cycle): the outcomes. The primer *ACS Principles and Practice for Simulation and Surgical Education Research* [42] provides many tips on how to approach the process.

Desired training outcomes and metrics need to be defined at the beginning, in order to guide the design process. These should be defined by the training program coordinator, in the case of an institution-specific course, or by an expert committee if proposed by a professional society. The initial framing opens the way to collect all the data required to develop the curriculum. It starts with a thorough literature review and development of an Anatomic Bill of Material, indicating all structures involved in the procedure. The analysis of best practices will separate choreography from safety considerations. A well-executed cognitive task analysis (CTA) [42, 43] allows us to document the series of decisions behind every single maneuver for a surgical procedure and the set of cues that need to be recognized to make those decisions [44–47]. It is usually completed by interviewing one or more experts while viewing a video of the procedure. Once completed, the CTA documents all steps of the procedure and, if appropriate, all phases of patient management in detail. It is the primary document used for all curriculum development work, didactic content, physical trainers, and assessment instruments.

The CTA frames the educational requirements, which can be translated into simulation requirements. Based on these, simulators on the market are reviewed. If none meet the requirements, a development team is tasked to address those needs and create one or more dedicated simulators. Afterwards, the simulators are verified and validated along with the associated curriculum. In case validity is shown and no major modification is required, the curriculum can be implemented into training courses.



| | | | | | | |
|---|---|---|---|---|---|---|

| How | Consensus conference | Standard curriculum template | Engineering physical simulator | Standard validation template | Current procedures | Issue mandates and certificates |

**Figure 75.5** Full life-cycle curriculum development template. *Source:* Richard Satava. Reproduced with permission of Richard Satava.

Multiple rigorous validation studies organized by professional societies can lead to the simulation being considered for credentialing. This could lead to certification that the learning objectives defined at the beginning of the development process have been reached [48, 49].

## Available and future simulation technologies

Learning objectives and desired training methods determine what kind of training is required and which simulators can be used. As identified in the full life-cycle curriculum development template (Figure 75.5), simulator selection/development always comes *after* "outcomes and metrics" and "curriculum development." Before considering the development of a new simulator, which can require considerable investment, one should review existing ones. Over the last decade the range of commercially available simulators for training healthcare professionals has grown exponentially. Training tools available for laparoscopic and robotic surgery range from physical and virtual to hybrid.

In the context of simulation, a concept that needs to be carefully examined and understood is that of fidelity. Although "simulation" is considered a reproduction of reality, it is an approximation of the tasks with some degree of fidelity. A *high-fidelity* surgical simulator aims to replicate the actual surgical setting, mimicking every detail from anatomy and physiology to tissue behavior. On the other hand, a *low-fidelity* trainer has the goal of focusing just on some specific detail, putting the rest aside. Thus, a cadaver could be considered an "organic simulator" that is closest to the surgical concept of high fidelity, while FLS/E-BLUS tasks, with their pegs and gauzes, are synthetic low-fidelity trainers. High-fidelity simulators, due to their complexity, are usually more expensive and require more time to be prepared for a training session, whereas low-fidelity ones are often more transportable, cheaper, and easier to arrange. Some exercises may be reproduced on both types of simulator; some others may not. Fidelity also needs to be seen in the context of the targeted learning objectives, which may change the definition of fidelity itself. Despite the level of fidelity, assessment capabilities also need to be considered, ranging from expert observation to embedded sensors or software-based assessment.

### Physical simulators

For laparoscopic training, the most common simulators today are physical. The first laparoscopic box-trainers were built in the 1990s and they are still produced in many different shapes (Figure 75.6). The concept is always the same, with a trocar-retaining upper wall and a base to host different exercises. A great variety of tasks have been developed, with FLS-related ones being the most common. Apart from the FRS dome, still not commercially available, and the FIRST tasks, validated basic skills physical simulators are not available in the robotic training field. These low-fidelity trainers lack embedded assessment instruments, but rely on time to completion and counting of errors to assess performance. Some more sophisticated trainers have been recently made available by the Center for Research in Simulation and Education Technologies (CREST; University of Washington, Seattle, WA, USA). These simulators target the intermediate training level as they reproduce parts of full procedures. These include the Major Vessel Injury (MVI) repair model [50] and the Pyeloplasty model [51, 52] (Figure 75.7), which can be used for both laparoscopic and robotic training. These models, in contrast to to many other physical models, have embedded assessment markers to objectively measure surgical skill. The MVI model, connected to a synthetic-blood bag, allows for objective measurement of blood loss, focusing on a clinically relevant measure. The Pyeloplasty model uses Black Light Assessment of Surgical Technique (BLAST) technology to objectively assess the alignment of the ureteropelvic junction. Similar tasks can also be performed, even without embedded assessment, on actual perfused

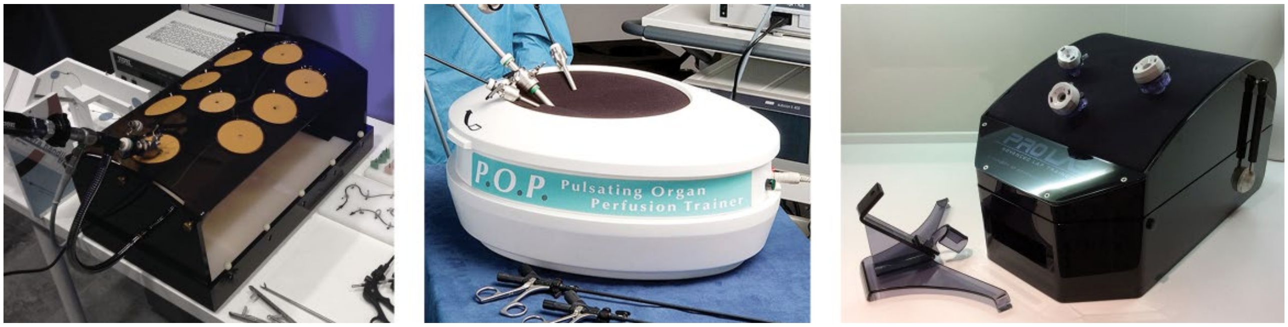

**Figure 75.6** Three laparoscopic box trainers: (from left to right) Szabo Berci, Pulsatile Organ Perfusion, Optimist (POP), and Pro Lab.

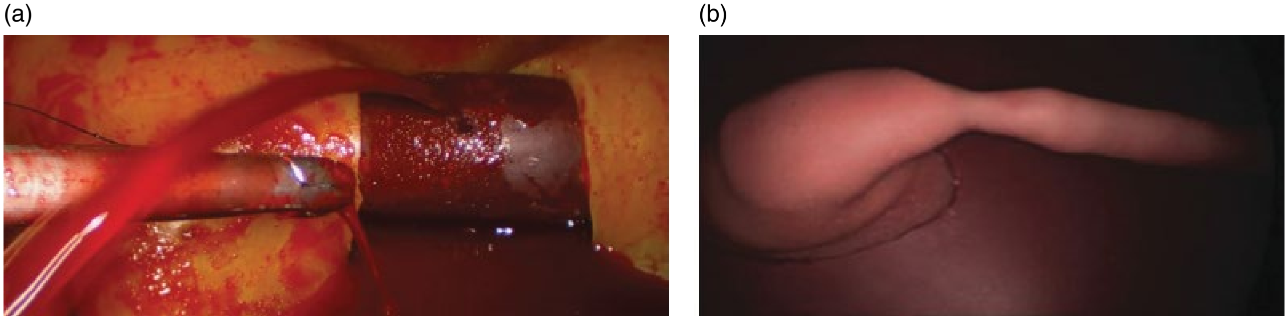

**Figure 75.7** Two Intermediate training tasks: (a) MVI repair model and (b) Pyeloplasty model by CREST. *Source:* CREST, University of Washington, USA. Reproduced with permission of CREST.

animal organs inside dedicated boxes like the Pulsatile Organ Perfusion, Optimist (POP) trainer (Innsbruck, Austria), and the Pro Lab (INTECH, Reggio Calabria, Italy), shown in Figure 75.6. When it comes to advanced, full procedural training, cadavers are often considered the gold standard of surgical simulators, although they present significant pitfalls. Indeed, they are not able to provide objective feedback about performance, as relevant damage could be caused without ever knowing it. This shortcoming of cadavers used as simulators has already been addressed in the automotive safety field and lead to the creation in 1976 of Hybrid III [53], the first modern crash-test dummy. Dummies have the ability to record an incredible amount of data, allowing a deeper understanding of what is happening to the driver during an automobile collison. Laboratory animals are often used for advanced training, although their anatomy is not a good analogue for the corresponding human one. Meanwhile, next-generation physical simulators are being instrumented to support real-time, objective assessment. Some attempts have already been made to create accurate synthetic anatomic structures representing the surgical space inside simple training boxes, to support repeatable *advanced* training without the use of organic or animal models. An example is the Radical Nephrectomy model by INTECH (www.intechsimulation.com), silicon-based and assembled over a 3D-printed structure. Mostly made of reusable parts, it was designed to fit inside a laparoscopic box-trainer. Finally, the US DoD has funded a major initiative for the development of an Advanced Modular Manikin(TM) open source, open standards platform that allows both technical and non-technical skills to be trained on a hybrid, full patient simulator being developed by CREST(Award# W81XWH-14-C-0101) (www.advancedmodularmanikin.com).

## Virtual reality simulators

VR simulators were considered the future of healthcare education in the early 1990s. After more than 20 years developers are still working to improve VR systems, to meet surgical education requirements. Realistic graphics and physics, as seen in videogames, although impressive are unfortunately not sufficient for surgery and very expensive to develop with current methods. Robot-assisted surgery simulators use VR today for basic tasks, like moving objects or suturing drills. Some intermediate training exercises for procedural task training are under development, as well as systems that allow for an interaction between the first operator from the console and a second operator maneuvering laparoscopic instruments. Robotic VR trainers (Figure 75.8) are on the market as stand-alone products or as upgrades for the actual robotic console.

## Hybrid simulators and future technologies

Hybrid simulators have been designed in the attempt to match the physical feedback of inanimate models to data collection and assessment capabilities of VR technologies. These systems, like the Electronic Data Generation for Evaluation (EDGE; Simulab, Seattle, WA, USA) or the LapX Hybrid (Epona, Rotterdam, The Netherlands), and the ForceSense (Medishield B.V., Delft, The Netherlands), are still just based on FLS tasks and take advantage of video tracking and several sensors to record performance and eventually assess in real time. This concept could be enhanced by applying augmented reality to synthetic models. The advent of three-dimensional printing is facilitating fast and cheap reproduction of physical models and instruments, which could accelerate adoption of technical skills training. This technology, coupled with biologic printing materials [54], could lead to the creation of *standardized* printed organs, designed to address training requirements and producible on site.

Given the variety of simulators available, many learning objectives can be met today. These range from simple inanimate trainers like E-BLUS, up to Human Patient Simulators that allow training of team skills [55–58]. In any case, citing Richard Satava, “the simulator is just
